Keywords

BAC
Bacterial artificial chromosome vector that is used to clone large genomic DNA inserts of 100 to 300 kb.

Chromosomal Bands
Light and dark staining patterns along the length of the chromosome that are unique for each chromosome and are produced by differential binding of dyes.

Chromatin Fibers
Strands of complexed DNA, and proteins (histones) organized into compact nucleosomes that are disk-like structures 10 nm in diameter and comprise 140 to 146 base pairs of DNA wound around histone octomers.

Released Chromatin Fibers
Linearized 30-nm interphase chromatin fibers experimentally released from interphase nuclei.

Released DNA Fiber
Linearized DNA strands experimentally released from nuclei or chromosomes serving as target for high-resolution FISH mapping.

FISH
Fluorescence *in situ* hybridization is the technique of localizing fluorescent nucleic acid probes (DNA, RNA) to complementary sequences of target DNA on a glass slide and visualizing them in a fluorescence microscope.

Interphase Nuclei
Nuclei that are between one mitosis and the next and contain decondensed chromatin.

Metaphase Chromosome
Fully condensed chromosome present at the mitotic stage (metaphase) in which chromosomes are attached to the mitotic spindle but have not yet segregated to the opposite spindle poles.

PAC
P1-derived artificial chromosome vector used to clone large genomic DNA inserts of 130 to 150 kb.

YAC
Yeast artificial chromosome vector used to clone large genomic DNA inserts of a few hundred kb to 1 Mb.

Gene mapping by fluorescence *in situ* hybridization (FISH) is the localization of a unique DNA sequence (probe) to a specific position (chromosomal band) within the genome (target). The DNA probe localization on the target is visualized using a fluorescent reporter molecule directly or indirectly bound to the probe. Although gene mapping by FISH usually refers to the localization of a gene or DNA sequence to a specific metaphase chromosome band, it can also include the relative position of genes along a chromatin or DNA fiber, or the identification of specific genomic BAC/PAC clones present in an array. FISH combines the specificity of recombinant DNA technology with basic cytogenetic techniques for target DNA preparation.

Valuable information regarding the biological and/or clinical significance of a gene can be obtained by identifying its subchromosomal location in both normal and disease conditions. Mapping a gene to certain critical chromosomal regions that may be deleted, amplified, or involved in translocation breakpoints can provide important information about the role of that gene in disease processes and may have significant clinical applications. Important information regarding gene function can also be obtained from mapping genes from individual tissues or disease states, identifying transgene insertion sites, studying interspecies synteny, and determining the order of and distance between two or more genes within a chromosome band.

1 Introduction

Fluorescence *in situ* hybridization (FISH) combines the chromosome preparation and banding techniques of classical cytogenetics with recombinant DNA technology. Specific DNA sequences (probes) when denatured will form a heteroduplex with denatured DNA on a glass microscope slide (target), and the resulting hybridization is visualized by a fluorescent reporter molecule (Fig. 1). The use of fluorescence over radioactivity as a mode of detection became feasible in the early 1980s when methods for labeling nucleic acids with haptens such as biotin were developed. This indirect approach to visualizing hybridized probe requires further detection steps with fluorescently labeled reporter molecules such as avidin or specific antibodies. Direct incorporation of fluorochromes into nucleic acids has now greatly simplified detection.

The first gene was mapped to human metaphase chromosomes using FISH in the mid-1980s, and now over 5000 articles utilizing gene mapping by FISH have been published. FISH is one of the few mapping techniques that does not require clones to overlap, to be positioned and ordered, and thus has broad applications in positional cloning studies. FISH now plays an important role in confirming *in silico* mapping information obtained through the human genome project, which has produced genome sequence databases for both human and other species.

FISH can localize a single gene to a subchromosomal band, can allow ordering of several genes within a chromosome band, and can aid in determining locus copy number, probe chimerism (YACs), pseudogenes, and location of gene family members. FISH mapping resolution is dependent on the level of chromatin condensation present in the target DNA and covers a wide range from high-resolution DNA fiber mapping (1–5 kb) to metaphase chromosome mapping at a resolution of 1 to 2 Mb, making it an exceptionally versatile mapping tool.

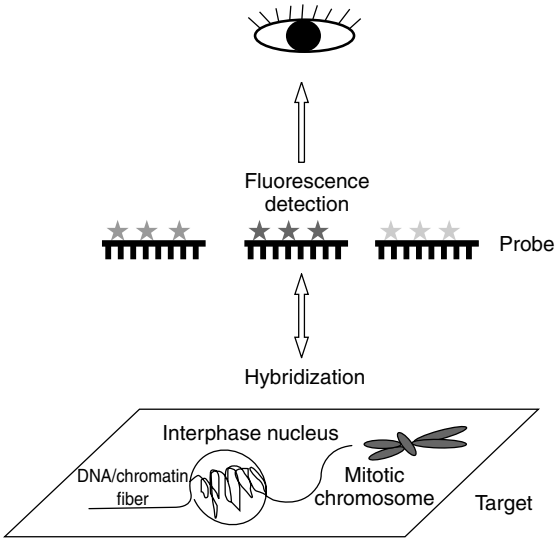

Fig. 1 Schematic representation of FISH. Basic FISH protocols consist of (a) preparation of target DNA in the form of metaphase chromosomes, interphase nuclei, or DNA/chromatin fibers on a slide; (b) labeling of probes directly with a fluor or indirectly with a hapten followed by a secondary fluor; (c) hybridization of the probe to the target; and (d) detection of the fluorescent hybridized probe under an epifluorescence microscope. (We acknowledge Dr Christine Ye and Miss Wei Lu for their help with the diagram.)

2
Probes for Gene Mapping by FISH

2.1
Identification of Probes from Genomic Databases

The human genome project has provided a wealth of data regarding DNA sequences suitable for gene mapping by FISH. Several databases containing information about expressed sequence tags (ESTs) and genes that have been sequenced or partially sequenced are available publicly on the World Wide Web. It may be necessary to search several websites in order to determine the relationship and ordering of these clones as no single database currently contains all this information. Although the quality of the clones is variable, use of these databases and *in silico* methods provide the best initial approach to identifying or localizing a particular DNA sequence to a chromosomal band or region. Validation of the localization can then be performed by FISH using a corresponding genomic DNA probe. Libraries containing bacterial artificial chromosome (BAC), P1 artificial chromosome (PAC), yeast artificial chromosome (YAC), and cosmid clones are now available for most of the human genome, and confirmation of the physical chromosomal location of these DNA sequences by FISH mapping is extremely useful.

There are several approaches to identifying clones (probes) suitable for human FISH mapping on the web. The first is to use the cytogenetic location. One can search for premapped FISH probes using the Genome Database http://www.gdb.org/hugo/ under ''Chromosome Resources'' and clones based on cytogenetic position can be obtained using one of the three following sites:

Genome database site: http://www.gdb.org/gdb/regionSearch.html,
GeneCards: http://bioinfo.weizmann.ac.il/cards/index.html, or
Genetic Location Database: http://cedar.genetics.soton.ac.uk/public_html/gmap.html.

A second approach is to obtain BAC, PAC, and cosmid clones specific for a particular gene or DNA marker by searching either the Genome Database (http://www.gdb.org) or the Locus link (http://www.ncbi.nlm.nih.gov/LocusLink/). In each case, the gene or marker name can be used to link to a DNA sequence database that can be screened to identify the clone name. For YACs, a similar approach is used at the Whitehead/MIT website (http://carbon.wi.mit.edu.8000/cgi-bin/conyig/phys_map) to identify both the clone and the contig containing overlapping clones along the chromosome.

To search for a corresponding genomic clone by gene or marker sequence, the sequence can be retrieved from a text search of http://www.ncbi.nlm.nih.gov:80/entrez/query.fcgi?db=Nucleotide. The accession number or DNA sequence can then be copied and pasted into http://www.ncbi.nih.gov/blast/blast.cgi and databases NR (finished sequences), HTGS (rough draft sequence), or GSS (overlapping BAC ends) screened for those containing the corresponding genomic clones. If identification of nearby or overlapping clones is required, this can be achieved on the basis of knowing the BAC clone (1) name or sequence (http://www.TIGR.org/tdb/humgen/bac_end_search/bac_end_intro.html), (2) fingerprint patterns (http://genome.wustl.edu/gsc/human/human_database.shtml), or (3) DNA sequence alignment [(Ensembl (http://www.ensembl.org/), NCBI (http://

www.ncbi.nlm.nih.gov/cgi-bin/Entrez/hum_srch?chr=hum_chr.inf), or UCSF (http://genome.ucsc.edu/)].

Once the specific clones or sequences have been identified, there are several sources from which they can be obtained and the websites are listed as follows:

Cosmids, BACs, PACs, and YACS

- The Centre for Applied Genomics (http://tcag.bioinfo.sickkids.on.ca/) – Canada
- DHGP (http://www.rzpd.de/) – Germany
- HGMP Resource Centre (http://www.hgmp.mrc.ac.uk/) – UK

BACs, PACs, and YACs

- TIGEM (http://www.spr.it/iger/home.html) – Italy
- Research Genetics (http://www.resgen.com/) – USA
- Genome Systems (http://reagents.incyte.com/) – USA

BACs and PACs

- Sanger Center (http://www.sanger.ac.uk/HGP/) – UK
- Pieter de Jonge's lab (http://www.chori.org/bacpac/) – USA

Genome databases are also available on the web for other species such as: http://bos.cvm.tamu.edu/bovgbase.html (cattle), http://ratmap.gen.gu.se/DownloadGeneData.html (rat), and http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=unigene (EST data for mouse, cow, zebra fish, clawed frog, fruit fly, and mosquito as well as wheat, barley, maize, and cress) as sources for genomic clones for FISH mapping.

2.2 Probes for FISH Mapping

The probes for FISH range from chemically synthesized oligonucleotides to total genomic DNA. Typically, DNA sequences used for FISH mapping should be of such a size and nature as to be readily visualized by a fluorescence reporter molecule under a 60 or 100× objective of an epifluorescence microscope. The two most common single-copy probes used in mapping experiments are cloned genomic sequences (YACs, BACs, PACs, cosmids, and plasmids) and enzymatically amplified unique sequences of cDNAs and expressed sequence tags. In all cases, the probe purity, type, and size are critical considerations for optimal mapping results. The degree of probe purity required is dependent on the labeling method to be used. The type and size of probe affects the labeling approach, prehybridization treatment, and detection method.

2.2.1 Genomic DNA Probes

Cloned single-copy genomic probes range in size from ~5 kb (plasmids) to ~1 Mb (YACs) and their signal strength is usually directly proportional to their size. Genomic probes can be labeled by nick translation or PCR and are visualized by direct or indirect labeling (see Sect. 2.3). Since genomic probes consist of contiguous genome sequences, they contain both unique sequences specific for the gene or marker, and commonly repeated sequences (SINEs/alu, LINEs) interspersed throughout the genome. In order to visualize the chromosomal location of the unique genomic sequences, with minimal nonspecific hybridization background, the common repeat sequences must be suppressed or blocked prior to hybridization.

This is achieved by preannealing the probe DNA with competitor total DNA or Cot-1 DNA of the same species. Cot-1 DNA is genomic DNA enriched in the commonly repeated genome sequences that is commercially available but only for human or mouse. This suppression hybridization approach is essential for mapping genomic probes to their unique location on target chromosomes.

Among the single-copy genomic probes, BACs and PACs are used most frequently for FISH mapping due to the availability of BAC and PAC libraries, their stability, and appropriate insert size (100 to 200 kb) for easy visualization. YACs must be checked for chimerism prior to use as they tend to be unstable and have a high rate of noncontiguous coligated insert sequences. Consequently, caution must be taken when using YACs for mapping purposes.

Other genomic probes important in FISH applications in molecular diagnostics, human cytogenetics, and genomics that also have mapping related functions include total genomic DNA used in comparative genomic hybridization (CGH) and chromosome painting probes. The application of these probes and their role in genome mapping will be discussed in Sect. 6. Satellite tandem repeat probes recognizing chromosome-specific tandem repeat sequences in the chromosomal centromeric and telomeric regions can be used in conventional and quantitative FISH mapping studies to identify specific chromosomes and measure telomeric repeats.

2.2.2 Unique Sequence cDNA and EST Probes

Unique sequence probes are smaller (<5 kb) than genomic probes and contain only expressed exonic sequences. These probes do not require blocking of common repeat sequences by Cot-1 DNA. As these probes contain noncontiguous genomic DNA sequences, their signal strength is related to the size and structure of the gene target and thus can be unpredictable. The transcribed (expressed) sequences within a gene may comprise a number of large contiguous exons or a number of short, widely separated exons. The former configuration would have a higher likelihood of producing a visible signal compared to that of the latter for the same sized cDNA probe. Thus, both the size and organization of the gene can determine the mapping results and should be tested on an individual basis. In general, cDNA or EST probes are best visualized by indirect labeling techniques and tyramide amplification detection methods (see Sects. 2.3.2 and 4.3)

2.2.3 Synthetic Oligonucleotides

Chemically synthesized oligonucleotides are usually too small to be visualized as unique sequence probes in mapping studies. However, they can be used for detection of high-frequency tandem repeat sequences such as those found in alpha satellite, telomeric, and Alu repeats present in centromeres, telomeres, and chromosome bands. These probes can be important in determining the chromosome-specific location of single-copy probes, and as an alternative to chromosome banding (see Sect. 4.3.1), especially in species other than human or mouse. Specialized artificial peptide nucleic acid (PNA) probes that have a polyaminoethyl glycine backbone replacing the pentose-phosphate backbone have the advantage that they bind DNA more stably at low salt concentrations. These probes have been useful in quantitative examination of telomeric repeat sequence lengths.

2.3 Probe Labeling

2.3.1 Purification

Prior to labeling, the starting probe DNA must be purified. The labeling method determines the extent of the required chemical purity of the probe. For preparations to be labeled by nick translation, DNA purification procedures are required for removal of RNA, which, if present, would result in significant nonspecific background. PCR labeling methods do not require the same purity of DNA. If cloned probes are being used, it is usually not necessary to remove probe DNA inserts from the host vector DNA prior to labeling since vector DNA does not reduce the labeling efficiency of insert DNA and will not hybridize to mammalian DNA targets. Cloned genomic probe preparations are most often isolated and purified using standard CsCl or alkaline lysis procedures, or commercially available kits (Qiagen, Roche Diagnostics).

2.3.2 Labeling Methods

The goal of labeling a probe for FISH is to both incorporate labeled nucleotides into the DNA and to produce short DNA fragments of 100 to 500 bp. This fragment size allows probe access to target chromosomal DNA while maintaining high specificity. Longer fragments can result in reduced target access, producing reduced specific signal and increased background. Shorter fragments usually require reduced stringency wash conditions and may result in significant nonspecific chromosomal background.

Nick translation, the preferred method of labeling for most genomic probes, both introduces a labeled nucleotide into the probe DNA, and cuts the DNA into appropriate fragments. Nick translation combines a DNase I enzyme, which randomly nicks single strands of the DNA template producing available 3′ends, with *Escherichia coli* DNA polymerase I, which both removes nucleotides by its 5′-3′ exonuclease activity and incorporates nucleotides at the available 3′ ends by its 5′-3′ polymerase activity. The labeling mixture consists of probe DNA, the enzymes DNAse 1 and DNA polymerase 1, a dNTP mixture and a fluor, aminoallyl, or hapten-coupled nucleotide (Table 1), usually in final volume of 100 µL or less. The reaction mixture is placed in a 15 to 16 °C water bath, for 1.5 to 2 h or longer depending on the labeled nucleotide being incorporate. Following incubation, the reaction is placed on ice and the size of the labeled fragments checked by electrophoresis on a 1.5 to 2% agarose minigel containing ethidium bromide. A standard sizing ladder should be included in the run. Samples can be heat-denatured prior to loading on the gel, but this is not necessary. If the fragment size is too large, the reaction can be continued with further incubation; if the fragment size is too small, the labeling procedure must be repeated for a shorter time. If the fragment size is within the correct range, the reaction is stopped by addition of 0.5 M ethylenediaminetetraacetic acid (EDTA), pH 8.0. High prime or random primer labeling is another less popular approach that may provide a higher efficiency of labeled nucleotide incorporation, but fragment size cannot be well controlled, and further digestion by DNase I is often required. PCR labeling using specific primers can be performed when amplifying DNA from any source, but requires some knowledge of the probe sequence. Alternatively,

using degenerate oligonucleotide primer (DOP)-PCR, complex probe libraries such as chromosome-specific painting probes can be prepared and labeled by incorporation of fluor, hapten, or amine group-derivatized nucleotides.

The type of labeling usually depends on the size of the probe and/or the target.

1. *Direct labeling*: Single-copy genomic probes such as PACs, BACs, or YACs that are >100 kb, and probes for large targets such as alpha satellite repeats, can usually be detected by the direct labeling approach. Fluorochrome-coupled or aminoallyl-derivatized nucleotides that bind amine reactive fluorescent dyes can be obtained commercially or prepared in the laboratory and are incorporated into probe DNA by nick translation, sequence-specific PRC, or DOP-PCR labeling. Fluorochrome-labeled DNA probes usually do not require further detection/amplification systems, however,

antibodies directed against some fluors are available if further amplification is required.

2. *Indirect labeling*: Unique sequence cDNA, EST, and smaller genomic probes (cosmids and plasmids) are too small to be visualized directly and require some form of amplification. These probes are best labeled with a hapten such as biotin or digoxigenin (DIG), which must be further reacted with a fluorescent reagent to be visualized. DNA probes labeled with biotin or DIG-conjugated nucleotides require secondary detection systems involving fluorochrome-labeled avidin or anti-DIG antibodies. In general, although direct labeling is usually a longer process then indirect labeling, detection is significantly expedited. The most common fluors and haptens used for FISH mapping are shown in Table 1.

2.3.3 Postlabeling Purification and Storage

Following the labeling process, the labeled DNA is purified by ethanol precipitation or with spin columns. Addition of carrier DNA (salmon or herring sperm DNA) or glycogen increases the yield of DNA during ethanol precipitation and reduces nonspecific background binding to both the target DNA and the glass slide. Genomic probes also require suppression hybridization with competitor Cot-1 or genomic DNA to block the common interspersed repeat sequences present (see Sect. 2.2.1). Following precipitation, the probe is centrifuged, washed with cold 70% ethanol, recentrifuged, and air-dried. The DNA pellet can be left as a dry pellet or resuspended in distilled water, Tris EDTA (TE) buff, or hybridization buffer and stored at −20 °C.

3 DNA Targets for FISH Mapping

3.1 Metaphase Chromosomes

Metaphase chromosomes have been widely used to assign a chromosomal map location to the many genes and DNA sequences (both human and other species) arising from the human genome project. Genomic DNA in the form of metaphase chromosomes is in its most condensed state and mapping resolution is limited to interprobe distances of >1 Mb. Localization of a single labeled probe on a chromosome can be determined by either the relative position of the signal along the length of the chromosome, or by its localization within a specific chromosomal band. Relative positioning is achieved by measuring the distance between the telomeric end of the p arm (pter) and the probe as a fraction of the total chromosome length (Flpter, or fractional length from the pter). Difficulties with this approach include nonuniform condensation along the chromosome and the presence of repeat sequence length polymorphisms in different individuals. This method has, for the most part, been replaced by band or subband localization.

Reproducible banding patterns unique for each chromosome have been developed using DNA staining procedures. Banding techniques that allow simultaneous visualization of the probe signal and the banding pattern provide an efficient and precise approach to metaphase gene mapping.

Multicolor probes can be used to visualize the order of several genes or markers along metaphase chromosomes. The labeled probes must be separated by at least 1 Mb to be distinguished, but since most chromosomal bands are several Mb

in width, ordering probes within a single band can be accomplished by this multicolor FISH. Mapping to telomeric and centromeric regions should be performed with caution and verified by other approaches, as chromatin folding in these regions tends to produce artifacts and order changes.

3.1.1 Metaphase Chromosome Preparation

The most common source of human and large mammal metaphase chromosomes suitable for gene mapping is mitogen-stimulated short-term cultures of peripheral blood lymphocytes. Amniocyte cultures, fibroblasts, lymphoblasts, and cell cultures can also produce good results. For mouse and rat, bone marrow, spleen, lymph nodes, and thymus are commonly used for chromosome preparation. For precise mapping, high quality, well-spread chromosomes with distinct banding patterns are essential. Preparation of mapping quality metaphase chromosomes is based on minor modifications of standard cytogenetic techniques. Cell synchronization may be required for some types of banding (see Sect. 4.3.1) and usually enhances the number of cells in metaphase, however, it is generally not necessary for most mapping situations.

There are four basic steps involved in the preparation of metaphase chromosomes from cultured cells:

1. Stimulation of peripheral T lymphocytes by the mitogen phytohaemagglutinin (PHA).
2. Inhibition of cell cycle by addition of a mitotic spindle inhibitor (colcemid) to arrest the cells in metaphase, that is, when the genomic DNA is condensed into chromosomes.
3. Hypotonic swelling of the cells to reduce cytoplasm and enhance chromosome spreading.
4. Fixation to inhibit further swelling, arrest cell function, and preserve good cell morphology.

The following comments pertain to human cells, but can easily be adapted to other species. Heparanized peripheral blood should be cultured within three to four days of collection in a medium containing 1% PHA to stimulate the division of T lymphocytes. When the cultured cells reach maximum mitotic activity (within 60–70 h), addition of colcemid for 20 to 30 min prior to harvest disrupts spindle formation and arrests the cells in metaphase. In this phase of the cell cycle, the nuclear membrane disintegrates, allowing the chromosomes to disperse within the cell. Production of good metaphase chromosome spreads depends on both the concentration of colcemid and the length of exposure. Too long a treatment results in short, condensed chromosomes and tight metaphases unsuitable for mapping purposes. Some protocols for preparation of murine chromosomes omit colcemid altogether. For adherent cells, subculturing 48 h and feeding 24 h prior to harvest at 50 to 80% confluence can enhance the mitotic index, and addition of colcemid for a longer time (4–6 h to overnight) is suggested for optimal metaphase chromosome production.

If cell synchronization is required, methotrexate (amethopterin) can be added to growing cells. Methotrexate inhibits incorporation of thymidine into DNA, thus arresting the cells in early S-phase. Following the removal of the S-phase block and addition of thymidine or its derivative bromodeoxyuridine (BrdU), the

cells resume DNA synthesis and proceed through the cell cycle in a synchronized manner. Substitution of BrdU is used when replication banding is required (see Sect. 4.3.1).

Harvested cells are swollen with a hypotonic solution of KCl or medium to increase fragility and lyse any remaining red blood cells. The loss of nuclear membrane results in the release of chromosomes throughout the enlarged cells facilitating their dispersion. The cells are slowly fixed in methanol:glacial acetic acid to enhance nucleoprotein cross-linking and gradually dehydrate the cells, preserving them in the swollen state. Proper fixation is critical for good chromosome morphology and attachment to the slides. Improperly fixed cells may result in cell contraction and poorly spread tight chromosomes. Overfixation can result in probe and reagent penetration problems, whereas underfixation may result in loss of chromatin and chromosome morphology. The fixed cells can be stored as pellets in tubes containing fixative at $-20\,^{\circ}C$ for several months. Resuspension in fresh fixative prior to each use, and minimizing exposure to room temperature air prevents evaporation of methanol and fixative esterification due to uptake of moisture. The fixed cells are dropped onto clean, wet glass slides and allowed to run down the slide held at a 45° angle, and dried. Metaphase spreads should be aged at room temperature for at least two days before being used for FISH mapping. Slides can be stored at room temperature up to four weeks, or for several months at −20° in a sealed dry container.

Preparation of high-quality metaphase spreads with clear banding resolution suitable for mapping studies is dependent on many factors. Colcemid treatment and fixation, humidity, temperature, and drying time are all critical steps during slide preparation and affect chromosome spreading, morphology, and the degree of residual cytoplasm present on the slides. Residual cytoplasmic proteins and RNA can increase background and reduce visualization of signal. Under ideal conditions of temperature, humidity, and drying time, when viewed under a phase-contrast microscope, cytoplasm should not be visible and chromosomes should be dark gray with sharp borders. The use of commercially available controlled environment chambers has significantly improved the standardization of slide making.

3.2 Interphase Nuclei

Interphase nuclei mapping provides improved resolution for ordering probes situated too close to each other to be distinguished on metaphase chromosomes. Since the folding of DNA in somatic interphase nuclei is about 20× less than that found in metaphase DNA, the mapping resolution is increased to 50 to 100 kb, compared to 1 to 3 Mb in metaphase DNA. In certain regions of the genome, the distance between probe signals in interphase nuclei are proportional to their genomic distance, with a linear relationship existing between the mean square of the distance ($\leq$1.5 μm) and the genetic distance (<1–2 Mb). Since probes separated by >1 to 2 Mb do not follow this relationship because of chromatin looping, mapping such probes may result in incorrect distance measurements.

Somatic interphase mapping does not provide information on chromosomal banding localization or location relative

to the centromere or telomere region. Probe order, however, can be determined by two approaches: in the first approach, three or more probes labeled with a single fluor can be ordered on the basis of distance measurements (mean-square distance) of pairwise hybridization experiments provided they are in the 50 kb to 1–2 Mb range. Use of probes with a high hybridization efficiency and evaluation of $\geq$100 nuclei are necessary for statistically accurate mapping results using this method. In the second approach, three probes, each labeled with a different fluor, or combination of fluors, can be hybridized simultaneously and the visualized order of signals can be examined in at least 50 nuclei.

The use of pronuclei, produced by the *in vitro* fusion of hamster eggs with hamster or human sperm, can further increase interphase mapping resolution by ~3 times as they have a diameter of ~50 µm compared to 10 to 20 µm for somatic interphase nuclei. Thus, a resolution of 20 to 25 kb can be achieved.

3.2.1 Interphase Nuclei Preparation

Interphase mapping is best performed on G0/G1(2 N) fibroblast nuclei grown to confluence to reduce the number of G2 (4 N) nuclei. The presence of G2 nuclei in uncultured preparations (peripheral blood lymphocytes) makes results more difficult to interpret. Fibroblast nuclei are large and flatten well following hypotonic treatment allowing visualization of signals on the same plane of focus. Fibroblasts grown under standard culture conditions until they reach confluence should be left for a further 6 to 7 days at 37 °C until no mitotic cells are observed. The cells are washed in a citrate saline solution, trypsinized, and collected by centrifugation. The pelleted cells are then treated with a hypotonic solution of KCl or medium, fixed with careful addition of 3 : 1 methanol : glacial acetic acid, and stored as a pellet at −20 °C as described for the preparation of metaphase chromosomes. The fixed cells are dropped onto clean glass slides and as the fixative evaporates, the cells flatten. The cell concentration should be such that there are sufficient nonoverlapping nuclei for adequate analysis. The air-dried slides can be stored at room temperature for up to four weeks or longer at −20 °C in a sealed container containing desiccant.

3.3 Chromatin and DNA Fibers

High-resolution fiber FISH methodology was developed as a result of the demand arising from the Human Genome Project. In order to group the increasing number of genes being mapped during the early 1990s, and to provide order within the same chromosomal region (or band), a high-resolution mapping approach was developed. High-resolution mapping has allowed for the construction of a finely integrated genetic and physical map, forming the foundation for the sequencing phase of the Human Genome Project.

As mentioned earlier, signal resolution using metaphase chromosomes is significantly limited. Chromatin fibers are highly compacted, and a single, small chromosomal band can contain up to a few Mb pairs of DNA, and include many genes. To take advantage of the less compacted status of chromatin, methodologies have been developed to produce released chromatin or DNA fibers for direct visualization. Originally named ''free chromatin FISH,'' fiber FISH has demonstrated the feasibility of FISH signal

detection on extended chromatin fiber for chromosomal structure analysis and physical mapping. A variety of modifications to improve the original methodology, such as increasing the mapping resolution, simplifying the fiber preparation, reducing the length variation of released fiber, quantifying the measurements of FISH signals, performing multiple-color detection, and combining DNA-protein and codetection using released fibers quickly followed. Various names corresponding to the methods of fiber preparation include: extended chromatin or DNA fiber FISH, elongated chromatin FISH, DNA halo FISH, individual stretch DNA molecule FISH, direct visual hybridization (DIRVSH), quantitative DNA fiber mapping, and molecular combing. The original and alternative approaches are now collectively referred to as high-resolution fiber FISH.

3.3.1 Fiber FISH Target Preparation

The released fibers can be categorized as either chromatin fiber or DNA fiber according to the preparation protocols and the morphological features following DNA staining. However, in many cases, mixtures of both types of fibers are produced. Generally speaking, the harsher the releasing conditions, the more DNA fiber will be generated. Chromatin fiber can be further released into DNA fiber by changing the release conditions to strip chromatin proteins. Fibers that are generated from cloned DNA fragments or the molecular combing procedure will generate no chromatin fibers.

Each type of fiber has advantages and disadvantages in terms of resolution and coverage. The resolution of chromatin fiber FISH is around 20 kb with coverage up to a few megabases; the ideal range to study larger regions of the genome in detail. In contrast, resolution of DNA fiber FISH is a few kb with coverage around 200 to 500 kb, which is best suited to a small area requiring the highest resolution. Thus, it is necessary to choose the type of fibers according to the desired resolution and coverage. Often, a combination of both types of fiber is desirable. It should be noted that the use of chromatin fiber has a unique benefit based on the following two considerations. Chromatin fiber may be more useful than DNA fiber when a high-resolution approach is required to study DNA–protein complexes. In addition, when comparing pattern or size variations between homologous regions, it is easier to trace individual cells using partially released chromatin fiber than DNA fibers.

Chromatin fiber preparation Chromatin fiber preparation protocols are based on effective release of chromatin fibers without destroying the 30-nm chromatin fiber structure. Four typical approaches have been developed to achieve this purpose: (1) chemical treatment to interfere with chromosomal condensation; (2) alkaline buffer or extensive hypotonic treatments to lyse the nuclear envelope; (3) accumulation of late G2 or early G1 phase cells to generate free chromatin; and (4) physical stretching of the nuclei with a cell centrifuge to produce chromatin fibers.

The chemical treatment method was the original approach that was used to increase the frequency of free chromatin. Although the steps for this approach are tedious when compared to other methods, an advantage is that different drugs may be used to delineate the chromosome condensation process, an important strategy to study the high-order structure

of the chromosome. Preparation of chromatin fibers from cultured lymphocytes by drug treatment is accomplished by culturing lymphocytes for 48 to 52 h followed by short-term treatment with ethidium bromide (EtBr), BrdU, or mAMSA. Harvesting chromatin fiber uses the same standard protocols as for harvesting chromosomes. After checking the chromatin fiber density under phase-contrast microscopy, if it is determined that the fibers are too crowded on the slide, the concentration of the suspension can be adjusted by adding more fixation solution. Once a high-quality batch of slides is completed, they should be air-dried at room temperature for a day, and sealed in slide containers with parafilm. Slides may then be stored for several weeks at $-20\,^{\circ}C$. It should be noted that irreversible damage occurs to chromatin fiber slides that are overdehydrated. Fixed free chromatin suspensions can be stored at $-20\,^{\circ}C$ for a much longer time.

A second approach to increase the amount of chromatin fiber uses protocols designed to open the nuclear envelope. The use of alkaline buffer to release chromatin fibers from cultured cells is based on the fact that nuclear lamins can be interrupted by high pH treatment, destabilizing the nuclear envelope, and rendering it susceptible to rupture by hypotonic treatment. Prolonged alkaline treatment can cause breakage of the nuclear envelope without hypotonic shock. Aliquots of a harvested fresh cell suspension are transferred into tubes containing alkaline buffer, and at various time intervals (3 to 5 min), the alkaline treatment is terminated by adding fixation solution followed by refixation. The fixed cell suspension is dropped onto slides and air-dried. Chromatin fiber density is checked using a phase-contrast microscope and the concentration of the suspension is adjusted accordingly. The optimal alkaline treatment for each particular cell line has to be obtained empirically using a brief screening test.

Generating chromatin fibers by this approach is affected by many factors including the length of treatment by the alkaline buffer and the pH (10–11.5). In general, a high pH over a longer period of time promotes the lysis of nuclei. The optimal combination for a given cell line can be found by systematically varying the conditions. Excessive treatment should be avoided since it reduces the number of useful chromatin fibers because of aggregation that follows release from the nuclei, and it can destroy the 300 Å structure leading to the production of the naked DNA fiber. Optimal results are best obtained by fixing the chromatin fibers quickly before they become aggregated following the release from the nuclei. The use of a small volume of alkaline buffer and a large volume of the prefixation solution is also a good way to avoid aggregation of chromatin fibers.

A cytospin also works well for generating chromatin fiber for many cell lines. Cells are resuspended in CSK buffer, incubated for a short time on ice, and then spun onto a microscope slide using the cytospin. The slides are then rinsed with fixation solution and examined under a phase-contrast microscope to determine the chromatin quality. Optimal cell concentrations vary for different types of cells and should be adjusted accordingly.

It should be noted that different protocols and even the same protocol will generate chromatin fibers with varied resolution, as it is difficult to control the releasing process that consists of multiple levels of DNA condensation. It is also common to obtain a mixture of 30-nm chromatin fibers and naked DNA fibers,

or fibers between chromatin and naked DNA including 10-nm chromatin fibers. An important step for fiber FISH detection is to include an internal marker probe of a known molecular size. By cohybridizing the probes in question with such a marker (using contrasting differential color detection), the size of the marker can be used to compare and measure the probes or regions in question. As long as an internal marker probe of known length is used, quantitative measurements can be performed, allowing the comparison of different chromatin fibers. For other types of analysis using fiber FISH where precise mapping information is not necessary, the use of a known marker for measuring purposes is not needed.

DNA fiber preparation Protocols for preparation of released DNA fibers fall into the following four categories: (1) complete release of DNA using detergent/alkaline treatment then linearizing fibers by gravity or by pulling with a coverslip; (2) generation of DNA fiber from a ''Halo'' preparation by protein extraction; (3) nuclear lysis and DNA release in a gel block then linearizing fibers by a mechanical or an electronic pulling force; and (4) linearizing DNA molecules by molecular combing. Two protocols that are very popular due to their simplicity and the quality of fibers produced will be described. The release of DNA fiber using alkali and linearization of the fiber by mechanical ''pulling'' is one of the simplest protocols to perform. Preparation of DNA fiber by pretreating cells within gel blocks and then mechanically ''pulling'' the fiber reduces interference from other nuclei. These two protocols should be useful as they exemplify most cases and can serve as a technical gate for additional protocols.

The first simple and popular method for preparing DNA fiber is the method of alkaline release and linearization of the DNA using mechanical pulling. Cells quickly fixed after hypotonic treatment are dropped onto a slide and treated with alkaline solution. One edge of a coverslip is placed on the slide and the coverslip is then pulled along the slide from one end to the other. The slides are ready for FISH after dehydration. The duration of alkaline solution treatment can be adjusted according to the desired release, with a longer treatment resulting in a greater amount of release from the nuclei. By adjusting the release conditions, this protocol can also be used to generate chromatin fiber. The alkaline solution can also be replaced with SDS-releasing buffer as described by others.

The second popular way of fiber preparation utilizes pretreatment of cells within gel blocks and mechanically linearizing the fiber. Lymphocytes are embedded in low-melting-point agarose and the resulting blocks of cells are treated with proteinase K and RNase A. A small piece of agarose-embedded DNA is placed at the end of a poly-L-lysine-coated slide. The slide is placed in a microwave oven, heated until the agarose melts, and the DNA is extended on the slide using a second slide that is pulled across the DNA fiber slide from one end to the other. The slide is then air-dried.

The fiber FISH molecular combing approach, that permits the stretching and aligning of deproteinized DNA on a solid surface, has recently drawn attention by demonstrating its effectiveness to high-resolution mapping. The advantage of this DNA fiber preparation method is the consistency of the length of prepared DNA fibers, an essential element of acceptable statistical analysis. Because of

the requirements of specific computer software and special instrumentation, this application has been limited to only a few research groups.

4
Denaturation, Hybridization, and Detection

4.1
Pretreatment and Denaturation

Prior to denaturation, pretreatment of slides with RNase and/or Proteinase K may be required to reduce signal background due to nonspecific binding, and to increase probe access to its target DNA. RNase pretreatment is usually required when using the counterstain propidium iodide, as it stains both DNA and RNA.

In order for probe DNA to bind to its homologous sequences on the target, both must be denatured, that is, made single-stranded. Denaturation of probe and target DNA can be performed separately or simultaneously. In either case, precipitated labeled probe DNA (see Sect. 2.3.3) is resuspended in a hybridization mixture containing formamide and dextran sulphate. Formamide destabilizes DNA such that it dissociates at a more convenient lower temperature than the normal "melting temperature." This is critical for maintaining target chromosome morphology. The concentration of formamide determines the stringency of the reaction, and a higher concentration should be used with repeat sequence probes to minimize cross-reaction. As oxidation of formamide can result in DNA depurination, it is critical that the formamide be of high quality, deionized, and have a pH of 7.0. Dextran sulphate changes the void volume increasing the "apparent" DNA concentration. If probe and target are to be denatured separately, the probe in hybridization buffer is placed in a 75 °C water bath for 5 min (genomic probes) or a 95 °C water bath for 10 min (unique and repeat sequence probes). Probes containing unique or tandem repeat sequences should be placed immediately on ice and added to the target as soon as possible. Probes requiring suppression hybridization must be denatured prior to the target DNA to allow for preannealing of the competitor DNA to take place. As discussed in Sect. 2.2.1, same species competitor (Cot-1 or genomic) DNA is added to any probe containing interspersed repeats to suppress the binding of these sequences to the homologous target repeat sequences. Slides containing the target DNA are denatured in 70% formamide for 2 min at 70 °C and immediately placed in ice cold 70% ethanol, dehydrated in 90 and 100% ethanol, and air dried. The denatured probe is then added to the slide, covered with a coverslip, sealed with rubber cement, and incubated at 37 °C overnight in a humidified chamber.

Alternatively, codenaturation of probe and target can be accomplished using a modified programmed slide warmer or PCR machine. The undenatured probe is added to the slide, covered with a coverslip, sealed with rubber cement, and placed in the slide warmer set to 70 to 95 °C. Both probe and target DNA are denatured simultaneously for 2 to 5 min, and the temperature is then ramped down to 37 °C for hybridization. This approach simplifies the denaturation procedure and minimizes handling of formamide, a toxic teratogen. Codenaturation is appropriate for probes not requiring the preannealing hybridization suppression step.

4.2 Hybridization

If probe and target DNA are denatured separately, the denatured probe is placed on the dried slide, covered with a coverslip, sealed with rubber cement, and placed in a humidified box in a 37 °C oven for hybridization. This temperature is critical for optimal hybridization. At temperatures below 37 °C, lower stringency hybridization can result, causing increased nonspecific chromosomal background signal. Conversely, higher temperatures may reduce signal intensity because of increased stringency conditions. If the slides dry out during this step, nonspecific background will be increased significantly. Although most probes are allowed to hybridize overnight, centromeric alpha satellite probes and some other larger genomic probes (BACs, YACs) may produce sufficient signal for visualization after 2 to 4 h. Hybridization timing should be determined empirically for individual probes.

4.2.1 Stringency Washes

Following hybridization, unbound DNA sequences are removed by washing with a solution of slightly higher stringency than that used for the hybridization. Stringency is determined by a combination of formamide concentration, temperature, and salt concentration. Varying any one of these will alter the stringency. Increasing the temperature and formamide concentration or lowering the salt concentration, all result in a higher stringency and require a more exact matching of probe and target sequence (lower % mismatched base pairing). Stringency conditions of hybridization and washing are key factors in optimizing the signal-to-noise ratio. If the stringency is too high, the background may be clean but may result in a weak signal; if the stringency is too low, high nonspecific background may obscure the true signal. Stringency conditions vary with the type of probe and target, and should be optimized for each mapping condition. The most common wash protocols use either a 50% formamide wash at a low temperature of 42 to 44 °C or a high temperature wash without formamide at 72 °C in 1 to 2x SSC (saline sodium citrate). Following the wash step, the slides can be counterstained and viewed immediately (direct labeled probes) or processed further for detection (indirect labeled probes).

4.3 Detection

Probes that have incorporated a fluorescently labeled nucleotide directly into the DNA sequence (direct labeling) can be detected immediately after the stringency wash and are thus the simplest to use. Biotin-labeled probes (indirect labeling) can be detected with reporter molecules such as avidin or streptavidin labeled with a fluorochrome. Signal amplification is achieved by addition of biotinylated anti-avidin/streptavidin antibody and another round of avidin/streptavidin labeled with fluorochrome. Similarly, DIG-labeled probes can be detected with an anti-DIG antibody followed by a DIG-labeled secondary antibody specific for the primary antibody and an anti-DIG antibody labeled with fluorochrome. Both systems work well for most probes. Although theoretically the number of rounds of amplification can be increased several times to enhance the signal, in reality, after one or two rounds, the nonspecific background increases substantially and lowers the signal-to-noise ratio. Instead, for weak signals or very small DNA probe sequences ($\leq$1 kb), another signal

amplification approach, termed *tyramide signal amplification* (TSA) or *catalyzed reporter deposition* (CARD) amplification, has been developed on the basis of the reaction of horseradish peroxidase and tyramine. A peroxidase-labeled hapten or antibody specific to the labeled probe is added to the bound probe, followed by biotinylated tyramine. The reaction of tyramine and peroxidase results in precipitation of a large number of biotin molecules at the site of probe hybridization. Biotin is then readily detected by fluorochrome-labeled avidin. This has resulted in successful localization of probes <1 kb in size.

Following the detection steps, slides can be counterstained directly or kept in the dark for 1 to 2 days at 4 °C in a 0.1 M phosphate buffer, pH 8.0 containing a detergent (0.05% NP-40). Slides should not be allowed to dry out before addition of the counterstain.

4.3.1 Counterstaining and Banding

The aim of physical mapping by metaphase FISH is to identify the specific chromosomal band to which the sequence is localized. This requires a method of visualizing both the gene or DNA sequence and the chromosomal bands simultaneously. Chromosomal bands range from 3 to 10 Mb in width and the number of bands per chromosomal spread can vary from 500 (low resolution) to 1000 (high resolution). Bands are named according to ISCN nomenclature and are numbered from the centromere to the telomere on each chromosome arm.

Several DNA binding dyes are available for staining chromosomes, some of which produce banding patterns similar to those produced in classical cytogenetics by the absorption dye Geimsa (G-banding). The two most common dyes (counterstains) used for chromosome banding following *in situ* hybridization are 4′,6′-diamidino-2-phenylindole (DAPI) and propidium iodide (PI). Other fluorescent DNA stains such as Hoechst 33258(QFH banding), quinacrine (Q banding), or a combination of chromomycin A3 and distamycin A (R banding) are infrequently used. Banding can also be achieved by cohybridization of PCR labeled long or short interspersed repetitive sequences (IRS) LINEs and SINEs (G-bands) or Alu (R-bands) repeat sequences.

DAPI binds to AT minor groove double-stranded DNA sequences and produces a reverse G-banding pattern with bright blue bands corresponding to AT rich, gene-poor regions and dark bands corresponding to GC and gene-rich DNA regions. Further treatment of DAPI-stained chromosomes with actinomycin D, or cell synchronization and incorporation of the thymidine analog BrdU into the late replicating DNA may enhance banding patterns in cases where the bands are not sufficiently distinct. Using software such as Adobe Photoshop to electronically invert grayscale images of DAPI-banded chromosome to the conventional G-banding pattern is also a convenient approach to chromosome identification. DAPI stain requires excitation by UV light and thus must be used with microscope systems that have a UV light source.

PI is a nonspecific double-stranded DNA and RNA intercalating (binding) dye that can produce an R (reverse)-banding pattern on metaphase chromosomes when cells in culture are synchronized by a thymidine block and then released from the block in the presence of BrdU. BrdU is then incorporated into the late replicating DNA (G positive, AT rich bands). Staining with Hoechst 33258 followed by UV irradiation reduces the PI staining of these bands, resulting in bright red staining

of the early replicating CG-rich R-bands and dark staining of late replicating G-bands. High-quality banding is dependent on appropriate synchronization, and the timing of the block release and cell harvest.

The choice of counterstain is in part determined by the fluorochromes used to label the probes being mapped. Probes labeled with red fluors such as TRITC, Texas red, spectrum Orange, Cy3 should not be used with target DNA counterstained with the red dye PI. DAPI can be used with both red and green fluorochromes and does not require cell synchronization for metaphase chromosome preparation. When using either counterstain, too strong a stain can obscure the banding pattern or result in a weakened probe signal. Both counterstains can be used on interphase nuclei and fiber FISH targets.

In order to preserve signal fluorescence, antifade chemicals such as ρ-phenylenediamine dihydrochloride have been developed to decrease fading caused by exposure to UV light. Antifade is usually combined with the counterstain and added to the slides after the detection step.

5 Microscopy and Image Analysis

Accurate mapping of genes by FISH is dependent on the spatial and spectral characteristics of the epifluorescence microscope, the sensitivity of the camera for capturing and recording images, and the digital-imaging resolution for analysis. High-quality epifluorescence microscopes equipped with a properly aligned high-intensity light source designed for high-light collection power (detection sensitivity) are essential for mapping analyses. The three commonly used light sources are mercury lamps, xenon lamps, and lasers. Mercury arc lamps are used most frequently as their emissions are similar to the excitation peaks of many commonly used fluors (254–646 nm). Xenon lamps tend to give a more even excitation across the 250- to 1000-nm range and are most useful with fluors excited above 700 nm. Both mercury and xenon lamps require filter sets that control the wavelength of light reaching the fluor. The most commonly used laser sources for FISH, argon ion lasers (emission 488 and 514 nm), and helium-neon lasers (emission 543, 594, and 633 nm), do not require excitation filters and only have a narrow range of emitted light, thus limiting their use to a restricted number of fluors.

The objective lenses must be of the maximum numerical aperture possible, of low self-fluorescing UV transmitting glass, and demonstrate minimum spherical and chromatic aberrations (apochromatic) to produce optimal sensitivity of fluorescent signal visualization. It is useful to have a range of objective magnifications – dry 10× and 20× for scanning metaphases and nuclei, and oil 60x and 100x for visualization and localization of the signal. A nonfluorescing oil must be used for the high-power objectives. Mixing oils from different sources may cause cloudiness, and use of oil stored for long periods of time can result in increased autofluorescence, both of which reduce signal visualization.

The interference filters should possess low autofluorescing properties and be properly aligned to reduce unwanted reflections. Filter sets for viewing fluorescence signals and counterstained chromosomes are determined by the fluorochromes that are being used and the type of mapping being performed. To map a single probe, narrowband pass

filters, which have optimized peak excitation and emission wavelengths for a single fluorochrome, are used to provide maximum signal intensity. Wideband pass filters are used in relational mapping to view two (dual-band pass) or three (triple-band pass) colors simultaneously. These filters result in a reduction of individual signal intensity due to ''bleed through'' of emission signals. The mechanism of switching excitation and emission filters to visualize the different fluors sequentially has been a critical issue for mapping with respect to proper alignment of signal with exact chromosomal location. Careful matching and mechanical adjustment, and use of internal reference microspheres, multiband pass filters, or automatic filter wheels have all been employed to minimize image shifts. Currently, automatic computer-controlled filter wheels and software packages that enable the capture of real-time images are used to minimize this registration problem.

Direct visualization of signals from small single-copy or unique DNA sequences is often difficult, even at high magnification (100x oil). Cooled charged-couple device (CCD) cameras are used for fine mapping studies as they provide excellent sensitivity, spatial resolution, and linearity with high dynamic range (12–16 bit). Cooling CCD cameras to minus 38 °C reduces dark current noise and background signals caused by the camera itself. Most high-resolution CCD cameras are cooled monochrome cameras that capture grayscale images based on light intensity. Grayscale images must be captured separately for each fluorochrome and transferred into an image analysis software program such as Adobe Photoshop for addition of color and merging. Modified color CCD cameras are also available, however, the spatial resolution is limited in the single-chip color CCD cameras with the result that some signals may be missed. The use of these cameras with real-time image capture and dual or triple filters eliminates the need for merging images. Further, image software has developed rapidly over the past decade and now facilitates quantitative FISH, automatic image focusing, acquisition at multiple wavelengths, visualization of multicolor probes, multicolor pseudocolor simultaneous imaging, enhancement of DAPI-banded chromosomes, chromosome classification, slide location of cells, fluorescence intensity, morphometry, image storage, and many forms of data tabulation making FISH mapping and FISH-based analyses more feasible in research and clinical laboratories.

6 Applications

The main function of gene mapping by FISH is the precise physical localization of genes of known biological activity. Although many genes and DNA sequences can now be positioned using *in silico* methods and the vast information available in the genome databases discussed in Sect. 2.1, visual verification is often required to finalize and verify the precise chromosomal location. Thus, FISH has played an important role in positional cloning as it is the most direct way to map and order DNA clones within a chromosomal band. To date, thousands of genes and markers obtained by standard cloning approaches have been mapped by FISH. FISH has also provided an effective approach for anchoring YAC and BAC contigs within a chromosomal band.

The resolution of FISH mapping depends on the degree of target DNA

Tab. 2 FISH mapping on DNA targets of increasing resolution.

Visual mapping of genes and DNA clones on		*Resolution*	*Application*	*Advantages (+) and disadvantages (–)*
Metaphase chromosome		1–3 Mb	Gene mapping on chromosomal regions; detection of translocations, hemizygosity and regional amplification; detection of chimerism or homologous regions; whole genome mapping (SKY/M-FISH, CGH and ZOO-FISH)	+ Telomere–centromere orientation + Mapping to specific band + Whole genome approach + Highest coverage + Chromosome identity –Low resolution
Interphase Nucleus		50–100 kb	Detection of translocation; visualization of chromatin domain interaction; monitor replication status; study gene amplification; ordering of clones	+ Distance measurement + Detect the level of gene amplification – Telomere-centromere orientation not possible – No chromosome identity

Released chromatin fiber		20–50 kb	Order of clones; visualization of the site of integration; mapping large chromosomal region with high resolution; DNA-protein codetection	+ High resolution + High coverage (20 kb–a few Mb) + Probe orientation with help of known markers – No chromosome morphological features
Released DNA fiber		1–5 kb	Ordering of clones; estimation of physical distance among probes; visualization of "gaps"; detection of size of deletion, amplification, and its orientation	+ Highest resolution + Probes orientation with help of known markers – Coverage is not high (1–a few hundred kb) – No chromosomal morphological feature

condensation, and spans several orders of magnitude ranging from 1 to 3 Mb on metaphase chromosomes, 50 to 100 kb in interphase nuclei, 20 to 50 kb on chromatin fiber, and 1 to 5 kb on DNA fibers. The type of target DNA used for FISH mapping will depend on the type of information required (see Table 2). Aspects of these three levels of gene mapping by FISH are presented in the following sections.

6.1 Metaphase Mapping

6.1.1 Single-copy Genes

Metaphase chromosomes present the most compacted form of DNA and thus provide the least-sensitive mapping resolution (1–3 Mb). Metaphase mapping has provided a subchromosomal banding localization for single-copy genes, viral insert sites, specific breakpoints, and regions of amplification or deletion. FISH mapping on metaphase chromosomes also orients genes relative to chromosome centromeres and telomeres. Key to metaphase FISH mapping is identification of true signal, the hallmark of which is a doublet signal on each chromosome (one per chromatid) of a homologous pair (see Fig. 2). The doublet signals must be visualized consistently at the same band location in each metaphase spread. The number of metaphase chromosomes needed to establish a chromosomal localization is determined by hybridization efficiency (% metaphases showing two pairs of consistent doublet signals). Hybridization efficiency is determined by the type and size of both probe and target DNA. Genomic BACs and PACs usually hybidize with >90% efficiency requiring analysis of 15 to 20 high-quality banded chromosomes. Smaller genomic probes (<10 kb) and cDNAs may show <20% hybridization efficiency and thus require analysis of more chromosomes (25–50).

Visualization of cDNAs can vary with the size of the target gene and its intron/exon

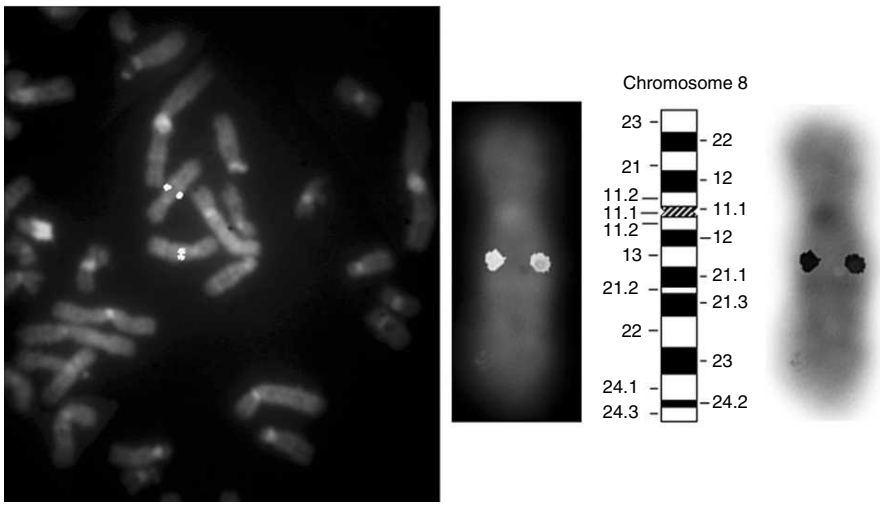

Fig. 2 Metaphase FISH mapping of a single-copy probe. Biotinylated DNA PAC probe (~100 kb) hybridized to normal human metaphase chromosomes counterstained with DAPI and detected with FITC. Doublet probe signals map to 8q13 on both chromosome 8 homologs.

structure, and usually requires amplification by approaches such as tyramide-based detection. Alternatively, cDNA screening of a PAC or BAC library can provide homologous genomic clones that are then easily mapped by FISH. Since one or more clones may be identified from such a screen, care must be taken in the interpretation of the results. Even if one genomic clone is identified, FISH mapping may result in either localization to a true mapping site on a single chromosome, or localization to two different chromosomes, suggesting the presence of a double or chimeric clone. In situations when several PAC/BAC clones are identified for one cDNA, PCR verification of the insert sequence should be performed prior to proceeding with FISH mapping. If two or more "verified" clones still result, localization to the same chromosomal site would indicate the true mapping site and redundancy within the library, whereas localization to different chromosome sites would suggest the presence of a gene family or a pseudogene. Since PAC/BAC libraries are publicly available (see Sect. 2.1), this approach has the advantage of providing both genomic clones and localization data for expressed sequences. FISH mapping on metaphase chromosomes is also a straightforward approach to the identification of the presence of chimerism within YAC clones, which are noted for their high rate of chimerism. Doublet hybridization signals at more than one chromosomal location indicate the presence of a chimeric clone and further analysis by somatic cell hybrids or other molecular techniques is advised.

Although the resolution of metaphase FISH is usually not sufficient for the fine mapping requirements of positional cloning, it provides an initial banding assignment that can be followed by more precise FISH mapping obtained with released chromatin or fiber FISH (Sect. 6.3). It should be noted that mapping in the subtelomeric and pericentromeric chromosomal regions is less accurate and should be avoided or used with caution as chromatin folding and duplications in these regions can result in inverted and/or erroneous ordering of probes.

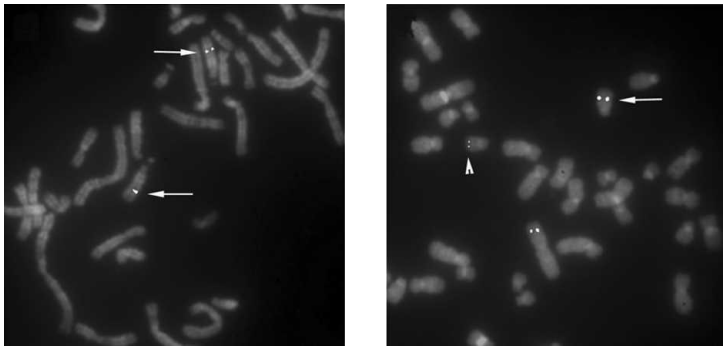
6.1.2 Segmental Duplications and FISH Mapping

The presence of segmental duplications $\geq$1 kb with 90 to 98% identity has been reported to comprise 3.6% of the genome and has been the cause of some physical mapping ambiguities. These duplications show a strong pericentromeric and subtelomeric bias of approximately 5- to 10-fold, however, this clustering of duplications in the pericentromeric and subtelomeric regions is not uniformly distributed among all the chromosomes. BAC clones containing these duplicated sequences tend to be found more frequently in unordered and misassigned contigs as their chromosomal localization is difficult to assign. FISH mapping of BAC clones containing interchromosomal duplications has been used to determine their coverage and duplication patterns. Less than half the chromosomes positive by FISH have a corresponding chromosomal localization of these clones by BLAST sequence identity. FISH mapping data can thus be used as a standard with which to identify chromosomal localization of these duplicated sequences, and to compare the assembly completeness and accuracy of interchromosomal duplications.

6.1.3 Relational Mapping

Relational mapping is used when the order of two or more genes localized to

the same chromosomal band or region is important. A probe's relation to a cryptic deletion or amplification, a specific breakpoint (Fig. 3), or confirmation of probe order (Fig. 4) based on computational approaches, are situations in which FISH can provide valuable information. The condensed nature of metaphase DNA requires probe sequences to be separated by at least 1 Mb of DNA, and at least 25 metaphases should be scored for statistically accurate results. Multicolor probes are usually used for this type of analyses and the number of genes that can be mapped simultaneously will depend on fluorochrome availability and filter capabilities of the microscope. Mapping probes relative to a specific chromosomal breakpoint can provide information regarding their biological and/or diagnostic

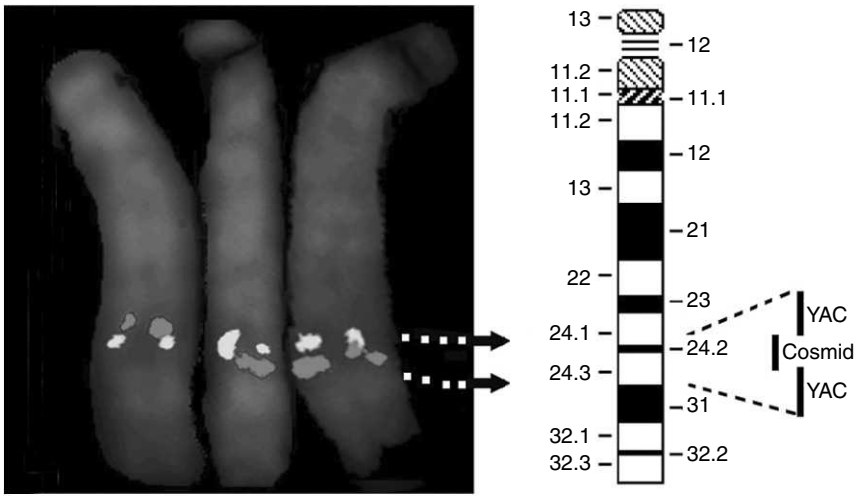


(a) (b)

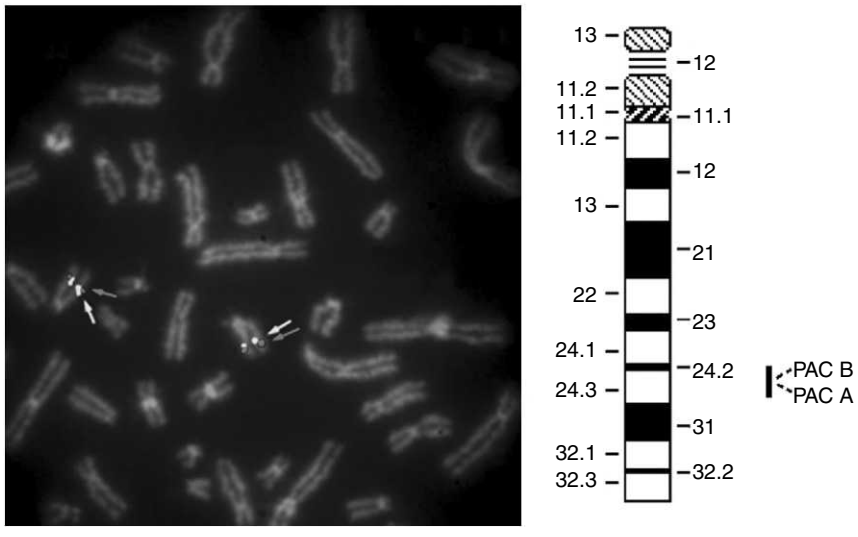
Fig. 3 Mapping across a chromosome breakpoint. (a) A cosmid probe (14 kb) hybridized to normal human metaphase chromosomes showed doublet signals at 14q24 on both chromosome homologs. (b) Hybridization of the same cosmid probe to metaphase chromosomes from a patient with a 2 : 14 (p25;q24) translocation. The probe demonstrates doublet signals on both normal (arrow) and derivative (arrowhead) chromosome 14 as well a doublet signal on the short arm of derivative chromosome 2 (no arrow). A consistently stronger signal was noted on der2, indicating that the breakpoint is located closer to the proximal (centromeric) end of the cosmid. (From Barbara G. Beatty, Stephen W. Scherer. (2002), FISH: A Practical Approach reprinted by permission of Oxford University Press).

Fig. 4 Relational mapping on metaphase chromosomes using two fluorochromes. (a) Three probes: Pairwise mapping was used to order two YACs and one cosmid probe within a YAC contig, which mapped to 14q24.2–24.3. The two YACs were labeled with DIG or biotin and the cosmid with biotin. DIG was detected with rhodamine (red) and biotin with FITC (yellow). Left chromosome: DIG-YAC 1 plus cosmid; middle chromosome: DIG-YAC 2 plus cosmid; right chromosome: Biotin-YAC 1 plus DIG-YAC 2. Thus, the order shown is YAC 1 – cosmid – YAC 2. Note: YAC 2 often demonstrated double-hybridization signals in a lateral orientation suggesting two domains of strong hybridization or clustering of Alu sequences within the YAC (see right chromosome). (b) Two probes: Two PAC probes localized to 14q24-31 by FISH were labeled with different haptens (DIG-PAC A and biotin-PAC B) and hybridized simultaneously to normal human metaphase chromosomes counterstained with DAPI. PAC A (detected with rhodamine, red) localized telomeric to PAC B (detected with FITC, yellow). [From Barbara G. Beatty, Stephen W. Scherer. (2002), Fish: A Practical Approach, reprinted by permission of Oxford University Press.] (See color plate p. xxiv.)

significance. Genes that span a breakpoint can be identified if the sequence length on either side of the breakpoint is sufficient to produce a visible signal as shown in Fig. 3. Mapping DNA probes relative to other chromosomal abnormalities, regions of amplification or deletion, or to tandem repeats can be performed using metaphase chromosomes, provided probes are available for the abnormal region and the distance between them is >1 Mb. It is worth mentioning that quantitative FISH (Q-FISH) has demonstrated its ability to study the length of telomeric repeats for individual chromosomes. Using FITC-PNA probes and quantitative



(a)



(b)

software, Q-FISH has been used to monitor changes in the telomeric repeats under different developmental, pathological, and disease conditions.

6.1.4 FISH Mapping Combined with CGH and spectral karyotyping (SKY)

With the development of the genome project, individual gene mapping has been expanded into genome mapping of chromosomal regions, whole chromosomes, and the entire genome. By combining individual gene mapping with entire genome or chromosomal FISH approaches such as CGH, which identifies regions of whole genome chromosome amplification and deletion, or SKY and M-FISH, which identify interchromosomal rearrangements, genes involved in these critical regions can be identified and localized.

CGH utilizes competitive hybridization of two probes (control and test) labeled with two different fluors onto normal metaphase chromosomes to reveal the presence and location of DNA copy number imbalances by comparing the relative signal intensities of each probe along the length of each chromosome. Special digital image analysis software programs developed to analyze and evaluate CGH data are available commercially. CGH has been particularly useful in identifying regions of DNA sequence copy number amplification and deletion in solid tumors. FISH mapping of single-copy or unique sequences within these regions can provide important information about the identification of candidate oncogenes and tumor suppressor genes respectively. Resolution of CGH on metaphase chromosomes is limited to several megabases. A significantly higher mapping resolution can be achieved using targets such as cloned DNA fragments (BACs, PACs, etc.) and cDNAs arrayed on glass slides. This high-resolution CGH, termed *matrix CGH*, can be used to map and study microdeletions and sequence overrepresentations.

Similarly, multicolor chromosome paint cocktails have now been developed for identifying interchromosomal rearrangements and mapping translocation breakpoints within the whole genome. Two commercially available approaches, SKY, and M-FISH utilize FISH probes derived from flow-sorted or microdissected chromosomes labeled by DOP-PCR (see Sect. 2.3.2). Each chromosome is identified by a unique spectral signature (SKY) or combination of fluors (M-FISH), permitting unambiguous identification of marker chromosomes and the different chromosome fragments involved in interchromosomal rearrangements. Sequential application of conventional G-banding and SKY on the same metaphase, as well as the combinatorial use of SKY and FISH, makes it possible to define the individual chromosomal bands involved in the structural rearrangements. Identification of putative genes or markers adjacent to or spanning specific breakpoints by *in silico* methods can then be verified and mapped by conventional FISH analysis.

6.1.5 Comparative Mapping by ZOO-FISH

Another application of gene mapping is the comparative mapping of map-rich species (human/mouse) with experimentally and economically important map-poor species (cattle, pig, horse, chicken). The location of conserved sequence segments between species can be visualized using composite chromosome-specific DNA probes (paints) from one species to hybridize to the chromosomes of another species (target). This cross-species painting approach is termed *ZOO-FISH* and has a resolution of approximately 7 Mb. The probes used are generally chromosome paints from

chromosome-specific libraries, but can be cDNAs or genomic probes (PACs/BACs) obtained from corresponding species-specific libraries. ZOO-FISH provides a mechanism for identifying major regions of conserved synteny between the two species being examined. This application of FISH has provided valuable information on regions of homology between the human genome and other map-poor species such as pig, chicken, and cattle, and between different members of a species including mammals, insects, and plants. It is expected that a better understanding of cross-species homologies will provide new models for the study of disease as well as new hypotheses of genome evolution.

6.2 Interphase FISH Mapping

FISH mapping using interphase nuclei provides a higher order of resolution than metaphase mapping and is used for clone ordering and generating physical maps with a resolution of <1 Mb. It is also useful for verifying distance measurements obtained from genome database contig information in the 50 kb to 1 Mb range. FISH mapping with pronuclei provides more precise ordering and estimation of genomic and physical distances and has been used in preparing high-resolution physical maps of chromosome 19. The concerns regarding pronuclei interphase mapping are that they are time consuming, laborious, and not suited to large-scale mapping approaches. Further, although the relationship between genomic and physical distance is considered linear from ~50 to 800 kb, the extent of DNA condensation within these nuclei cannot be controlled. Interphase mapping provides relative mapping distance measurements and should contain an internal control of markers a known distance apart. No information on chromosome location is provided by this approach.

6.3 Chromatin and DNA Fiber Mapping

Fiber FISH has demonstrated its advantages in a variety of applications. The majority of publications have involved physical mapping and chromosome structure studies of both plant and animal genomes.

Fig. 5 Sizing the "gap" in current physical map using fiber FISH: Two BAC probes were detected by two-color fiber FISH and the distance between two BAC probes represents the size of "gap".

These applications include: gap estimation for the current Human Genome Project as shown in Fig. 5; order and orientation for groups of genes/ESTs or DNA fragments; quantification of the size of amplified or duplicated fragments of special genes or chromosomal regions or integrated foreign inserts; identification or exclusion of genes or chromosomal regions defined by genetic markers; comparison of evolutionary conserved regions among various species; illustration of multiple repetitive sequences within chromosomal regions and direct visualization of genome organization; and length measurement of telomeric regions for the study of chromosomal packaging.

Keywords

Gene Targeting
The recognition and binding of a specific sequence in the chromosome of living cells by a reagent constructed for that application. The purpose may be sequence manipulation or modulation of transcription.

Homologous Recombination
A process through which disrupted replication forks are restored, double-strand breaks are repaired, and genetic exchange occurs.

Polyamide
A short term for a synthetic molecule consisting of pyrrole and imidazole units joined by amide linkages. These bind in a sequence-restricted manner in the minor groove of an intact duplex.

DNA Triple Helix
A three-stranded structure in which a third strand of nucleic acid lies in the major groove of an intact polypurine:polypyrimidine duplex. Binding is sequence-specific, and stabilized by hydrogen bonds between the bases in the third strand and the purine strand of the duplex.

Peptide Nucleic Acid (PNA)
DNA analog in which the sugar phosphate backbone has been replaced by peptide linkages.

The recognition and binding of a specific sequence in the chromosome of living cells by a reagent constructed for that application. The purpose may be sequence manipulation or modulation of transcription.

1
Gene Targeting

Gene targeting reagents bind specific chromosomal sequences in living cells. They can, or would, be used to manipulate genomic sequences for gene inactivation, modification, or restoration of function; suppress or activate gene transcription; deliver site-specific DNA damage; and probe chromatin and chromosome structure. Practical applications include the construction of transgenic cell lines and animals for research and commercial purposes. They are also under development as pharmaceuticals for the treatment of infectious diseases, gene therapy of genetic disorders and so on. Current strategies are based on either recombinant DNA technology (to produce DNA or protein constructs) or synthetic molecules that are based on oligonucleotides or natural product antibiotics. While many technologies are the subject of active research, only one, homologous recombination (HR), is widely employed at this time. In this review, we will discuss the current status of gene targeting strategies and challenges to the development of gene targeting reagents for use in mammalian, including human, cells. As will become apparent, most of the literature describes the work in progress.

1.1
The Problem

Gene targeting reagents must recognize and bind a specific DNA sequence in living cells, and be in residence long enough to provoke the desired outcome. Thus, a successful reagent must be stable in a physiological environment; be deliverable to the nucleus of the target cell; be able to bind a target in the context of mammalian chromatin structure; have orders of magnitude preference for the intended target sequence over any other sequence; and must find the target with sufficient frequency to be of practical use. Normal DNA metabolism requires sequence recognition for HR and the regulation of transcription. The molecules involved in these processes, DNA, and the proteins that regulate transcription serve as explicit models for some of the reagents under development. One fundamental consideration is the nature of the recognition process (Fig. 1). Reagents that recognize sequence in an intact duplex must do so from the vantage point of the major groove, which is rich in recognition sites, or the minor groove, which is relatively poor. Those designed to ultimately pair with the target sequence must engage a pathway through which the complementary strand becomes accessible and available for hybridization.

2
Homologous Recombination

2.1
Introduction

Targeted gene modification was first demonstrated in mammalian cells nearly 20 years ago. These initial studies targeted chromosomal genes in established cell lines and in mouse embryonic stem (ES) cells. Collectively, they laid the foundations for subsequent studies of gene function in cells and mice, and for the creation of mouse models of human disease. They also raised the enticing possibility that genetic defects might be precisely corrected as the ultimate approach to gene therapy. These considerations have provided the impetus to understand the

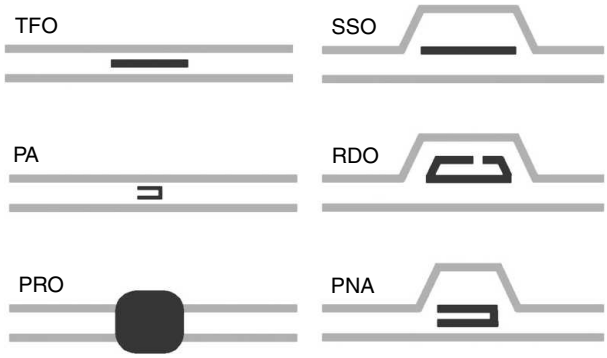

Fig. 1 Recognition of DNA sequences by various gene-targeting reagents. Targeting reagents either bind to duplex DNA or to the separated strands. Triplex forming oligonucleotides (TFOs) recognize their target DNA via interactions in the major groove. Polyamides (PAs) bind through the minor groove. Proteins (PROs) can make binding contacts in both grooves, although most commonly with moieties in the major groove. Single-stranded oligonucleotides (SSOs) pair with one of the separated strands and may mimic an intermediate in HR (see Fig. 3). It may be that small fragment homologous recombination (SFHR) proceeds through such an intermediate, but mechanistic studies have not been done. RNA:DNA oligonucleotides (RDOs) are envisioned to bind to both separated strands, but such binding has not been demonstrated. Peptide nucleic acids (PNAs) clamp onto one of the separated strands by Watson–Crick pairing and by forming Hoogsteen hydrogen bonds with moieties in the major groove of the PNA:DNA hybrid.

mechanism of gene targeting and to define the key experimental parameters for this technology.

Targeted gene modification can occur by HR and engages the cells own recombination machinery, which has been fine-tuned by evolution. For that reason, it possesses many of the attributes of an ideal system. HR occurs with very high specificity and selectivity, discriminating readily between genes that differ by only a few percent, and is extremely accurate, introducing very few errors. Two types of vectors – replacement (ends-out) and insertion (ends-in) – have been used for targeted recombination in mammalian cells (Fig. 2), with replacement vectors being far more common. The main drawback of targeted recombination in mammalian cells is low frequency; roughly 1 event per 10^5 to 10^7 treated cells under commonly used conditions. This presents a problem for therapeutic applications where targeted modification of a high fraction of a cell population is critical. Low frequency is less of a barrier for genome manipulation in proliferating cells in culture because the rare, properly modified cells can be identified and grown into a pure population. Nevertheless, a substantial increase in the frequency of targeted recombination would make genome modification less tedious and improve the chances for targeted gene

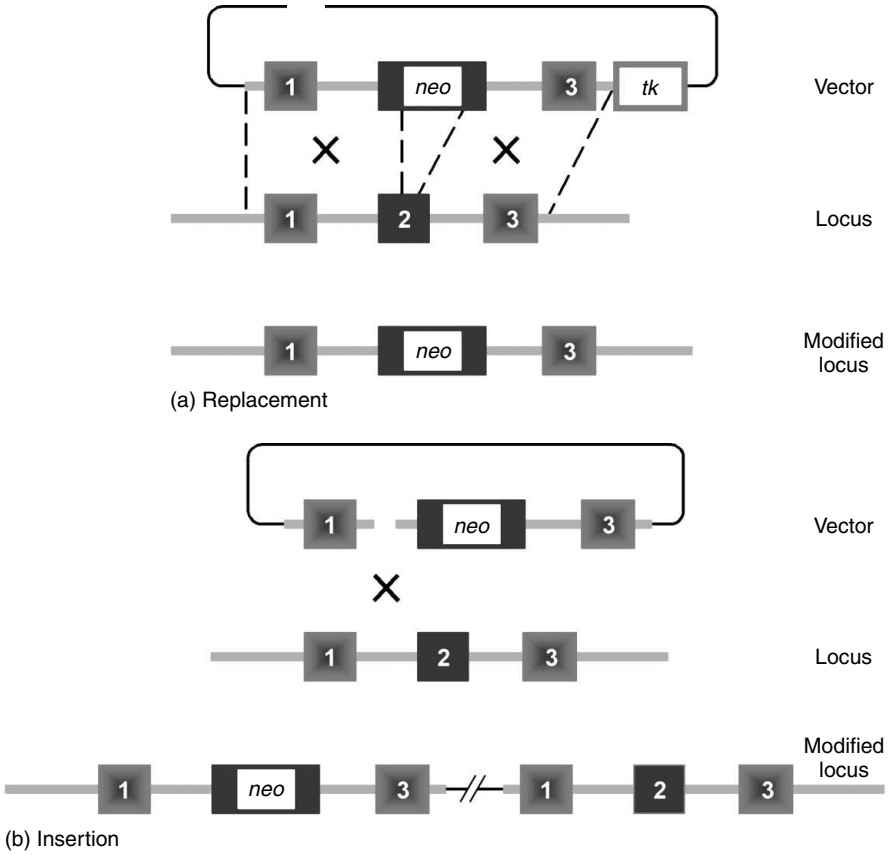

Fig. 2 Types of targeting vectors. (a) Replacement vector. Positive–negative selection is illustrated. Exon-2 is disrupted by incorporation of the gene for neomycin resistance (neo), which constitutes the positive selection marker. The herpesvirus *thymidine kinase* (*tk*) gene is included at one end of the homologous sequences and constitutes the negative selectable marker. The vector is linearized in the plasmid sequences (thin black line). HR in the homologous sequences on either side of the *neo* gene (indicated by Xs) replaces the chromosomal copy of exon-2 with the one from the plasmid vector. The *tk* gene is lost upon HR so that targeted cells survive selection against the *tk* gene. Random integrants (not shown) incorporate the *tk* gene and are killed by selection. (b) Insertion vector. The vector is linearized within the homologous DNA, in this instance between exons 1 and 2. HR at the double-strand ends inserts the vector into the locus, causing a duplication of the homologous sequences with the plasmid sequences located between the two copies. (After Muller, U. (1999) Ten years of gene targeting: targeted mouse mutants, from vector design to phenotype analysis, *Mech. Dev.* **82**, 3–21. Reprinted with permission of Elsevier Science Limited.)

therapy. Rational improvements depend on understanding the underlying process of HR. Clearly, genome manipulation cannot be the main function of HR in cells.

2.2 Repair of Broken Replication Forks

The initial demonstration that HR occurred in cultured mammalian cells was

somewhat surprising, as recombination had been thought about and studied mainly in the context of meiotic recombination during gamete formation in the germ line. Over time, it has become clear that HR in somatic cells is one of a number of cellular systems for dealing with DNA damage. It is specifically called into play when both strands of the DNA duplex have been damaged, as occurs, for example, with a double-strand break or when the strands have been cross-linked. Quantitatively, the most important role for HR is the recombinational repair of stalled or collapsed replication forks. In *Escherichia coli*, in the absence of the principal recombinase, RecA, about half the cells in a culture are dead, suggesting that a majority of replication forks are compromised in each replication cycle. In mammalian cells, with their much larger genomes, it is thought that replication forks stall more often, which is the likely reason why cells defective for the RecA homolog, Rad51, are inviable.

It is useful to consider, in overview, one of the ways by which HR can function to restart a broken replication fork because it provides an analog for the main reactions of targeted recombination. As shown in Fig. 3, when a replication fork suffers a break, or encounters one, it collapses, leaving a partially replicated duplex with a protruding single-stranded tail. With the aid of several accessory proteins, the Rad51 recombinase is loaded onto the single strand to form a helical filament of Rad51 with a central single strand of DNA. With the aid of additional accessory proteins, this structure coordinates the search for the corresponding sequence in the intact duplex. When the matching sequence is located, Rad51 catalyzes strand invasion, which pairs the invading single strand with

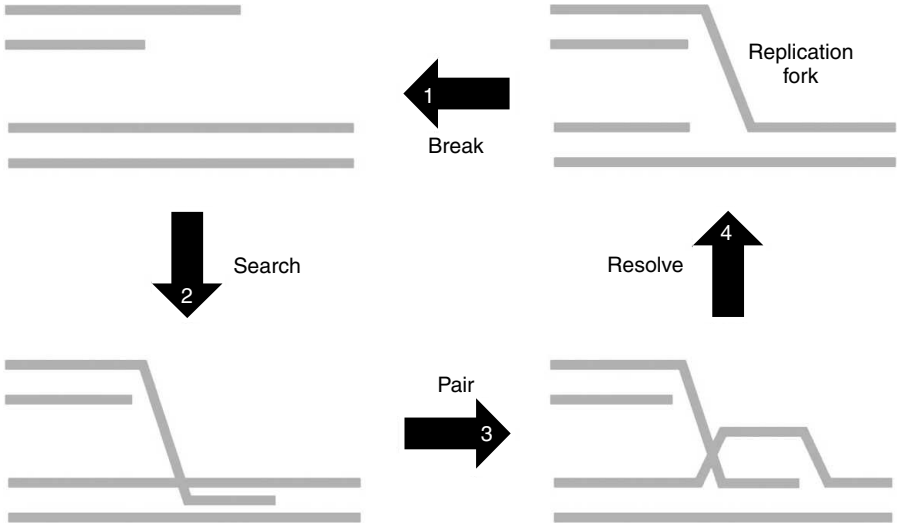

Fig. 3 Repair of a broken replication fork. The single-stranded tail at the broken end is coated with Rad51 recombinase, which then catalyzes the search for homology and the pairing of the single strand with its complement in the duplex. As shown in more detail in Fig. 4, this heteroduplex structure can be resolved by strand cleavage to regenerate a fork-like DNA structure. Several additional proteins are required to convert this branched structure into a functional replication fork.

its complement in the target duplex. This structure then serves as the substrate for a group of replication proteins that modify it to reconstitute the replication fork.

Two steps in this pathway – the search for homology and pairing with the complementary strand – provide structural analogies for the key steps in duplex recognition by all methods of gene targeting (Fig. 1). The search for homology and DNA pairing are thought to take place within the filament of Rad51 and single-stranded DNA, as originally proposed for RecA. In principle, the single-stranded DNA in the filament could approach the duplex DNA via the major groove or the minor groove. Studies using groove-specific DNA binding reagents, modified nucleotides, and cross-linkers, as well as structural analysis of the products, indicate that the initial attack most likely occurs through the minor groove. The search for homology is catalyzed by the recombinase, which binds to duplex DNA and transiently underwinds it, exposing the minor groove for interaction with the single strand in the Rad51 filament.

In the minor groove, there are insufficient hydrogen-bonding moieties to allow specific recognition of homology by base–base interactions. Instead, the recombinase apparently tests the single strand for homology with the duplex by catalyzing an exchange of pairing between bases in the duplex (mainly A and T) and those in the single strand. This trial pairing is accomplished by rotation of the bases through the minor groove in a plane perpendicular to the helix axis, breaking the Watson–Crick pairing in the duplex and reforming it, if possible, with the bases in the single strand. In regions of heterology, the imperfect pairing is rapidly reversed, allowing a new segment of duplex to be tested. When homology is encountered, the pairing between the single strand and its complement in the duplex is extended to form a heteroduplex (Fig. 3). The displaced single strand lies in the major groove of the newly formed heteroduplex. Although this is a triple-stranded structure, it is not the same as that in a triple helix, in which the duplex is intact (see below).

The search for homology and the formation of the heteroduplex intermediate are aided by Rad54 protein, which is a member of the Swi2/Snf2 family of DNA-dependent ATPases with helicase motifs. Rad51 and Rad54 interact *in vitro*. Rad54 acts upon the duplex target DNA to introduce negative and positive supercoiling. Domains of negative supercoiling around the target site would favor the unwinding of the duplex that occurs upon binding the Rad51 filament, which likely explains the ability of Rad54 to increase the efficiency of Rad51-mediated strand pairing. Both Rad51 and Rad54 are present in greater amounts in S-phase relative to the G1-phase, consistent with a role in the repair of replication forks.

2.3 Targeted Recombination

In its role in replication, HR must be nearly 100% effective in reconstituting broken or stalled replication forks. If the basic reactions of fork repair and targeted recombination are similar, then why are so few treated cells successfully modified? Examining some of the possibilities is illuminating; it records our step-by-step progress in understanding the nature of targeted recombination and points the way toward increasing efficiency.

One obvious difference between targeted recombination and fork repair is that the broken arm of a replication fork is already inside the nucleus, whereas the targeting

vector must be delivered from outside the cell. Two general methods – nuclear injection and mass delivery – have been used to introduce targeting vectors into cells. Early experiments using microinjection yielded about 1 targeted recombinant per 1000 injected cells. Mass delivery methods, which are vastly simpler and cheaper, typically yield targeted recombinants at frequencies 1000-fold less than microinjection. The basis for this difference is unclear. It does not appear to be a problem with transport to the nucleus, since 10 to 100% of treated cells can express genes transfected by the common methods of mass delivery such as electroporation, calcium phosphate precipitation, Fugene-6, and LipofectAmine. Thus, entry into the nucleus is not the fundamental barrier to efficient gene targeting.

A second, more subtle difference between targeted recombination and fork repair is the number of DNA ends. The broken arm of a replication fork has only one end, whereas a targeting vector has two. It was shown earlier on that linear vectors give several fold higher targeting frequencies than circular ones, as expected from targeting experiments in yeast. The presence of multiple ends, however, makes the transfected targeting vector a substrate for nonhomologous end joining (NHEJ), which along with HR is a major pathway for repair of double-strand breaks in mammalian cells. NHEJ operates throughout the cell cycle, whereas HR is prominent in mid to late S-phase and G2. A reasonable expectation is that NHEJ might compete with HR, effectively eliminating targeting substrates by circularization and multimerization. In addition, NHEJ is thought to be responsible for random integration, which occurs at roughly 1000-fold higher frequency than targeted recombination. The high background of random integration events can be minimized by any of the several tricks such as positive–negative selection that render most random integrants inviable (Fig. 2). Consistent with the idea that HR and NHEJ compete for substrates, repair of chromosomal double-strand breaks by HR is increased 2- to 25-fold when components of the NHEJ pathway are defective or inhibited. Surprisingly, however, neither the joining of transfected DNA ends nor random integration appears to be affected by the absence of NHEJ, and targeted recombination is not substantially increased. These observations and others suggest that there may be additional mechanisms for dealing with DNA ends. Although it is unclear to what extent NHEJ might affect recombination, the absence of a substantial effect in NHEJ-defective cells suggests that competition between NHEJ and HR is not the key to the low frequency of targeted recombination.

Another obvious difference between targeted recombination and fork repair is the proximity of the DNA to the target sequence. The DNA end at a broken replication fork is tethered in the general vicinity of the target sequence by virtue of its attachment to the oppositely directed replication fork. By contrast, the exogenous DNA must find its target among all the sequences in the genome: a daunting task. Nevertheless, the search for homology does not limit the frequency of targeted recombinants in mammalian cells. Varying the number of exogenous DNA molecules in the nucleus over a 1000-fold range (delivered by nuclear injection), or the number of targets in the genome by up to 400-fold had no significant effect on the frequency of targeted recombination. These counterintuitive results have been confirmed in competition experiments. Thus, the frequency of targeted

recombination is limited by something other than the search for homology. These results stand in stark contrast to those in yeast, where the process was found to be dependent on the number of target copies.

Targeted recombination and fork repair also differ significantly in the extent of homology, which, for the broken arm of a replication fork is as long as the replication bubble. For practical reasons, the length of homology in targeting vectors is limited to less than about 20 kb. Over this range, the frequency of targeting in mammalian cells shows a steep dependence on the length of homology, with a 2- to 3-fold change in length giving a 10-fold change in targeting frequency. Once again, these results are distinct from those in yeast, where gene targeting is linearly dependent on length of homology. They also stand in contrast to the linear length dependence of intrachromosomal HR in mammalian cells. The peculiar dependence of mammalian gene targeting on the length of homology suggests that the limiting step in the pathway is downstream of finding the target gene. In some undefined way, longer stretches of homology must exponentially improve the chances of a productive outcome.

Beyond the length of homology, there is also a potential difference in the quality of homology. A broken arm of a replication fork is identical to the intact arm (with the exception of very rare replication errors). The homologous segment of a recombination vector, however, is often isolated from nonisogenic sources and thus may carry nucleotide polymorphisms. Single-nucleotide differences between homologous sequences lead to mismatches in heteroduplex recombination intermediates. In bacteria, yeast, and mammalian cells, such mismatches reduce the frequency of HR in a way that is dependent on the mismatch-repair machinery and certain DNA helicases. In mammalian cells, use of nonisogenic DNA (up to about 1% different) can reduce the efficiency of targeting up to 20-fold. Although this can be a substantial effect, even isogenic DNA will function at very low absolute frequencies. In contrast to the effects of distributed mismatches, blocks of nonhomology at the ends or within the homologous regions (as shown in Fig. 2) have little or no effect.

Perhaps the most basic difference between fork repair and targeted recombination is the intended outcome. For reconstitution of the replication fork, the heteroduplex recombination intermediate must be resolved so that a fork is created (Fig. 4). For recombination, a further resolution is needed. Breakage of one strand at the fork can either release the exogenous DNA or integrate it into the chromosome to give a targeted replacement of the underlying DNA. In the parlance of recombination, release corresponds to a conversion event and integration corresponds to a crossover event. It is notable that repair of broken DNA in mammalian cells occurs with a very strong bias (up to 100-fold or more) against crossover events, perhaps as a protective mechanism against loss of heterozygosity. In mammalian cells, it seems that broken ends often invade a homologous duplex, prime DNA synthesis, and then disengage from the duplex. It is common to find randomly integrated targeting vectors that have been extended up to 10 kb or so at one or both ends by a prior homologous interaction with the target duplex. Thus, the inherent bias toward conversion-like resolution of targeting intermediates may constitute the principal barrier to gene targeting in mammalian cells.

The view that a preference for conversion limits the frequency of targeted recombination is supported by results in which

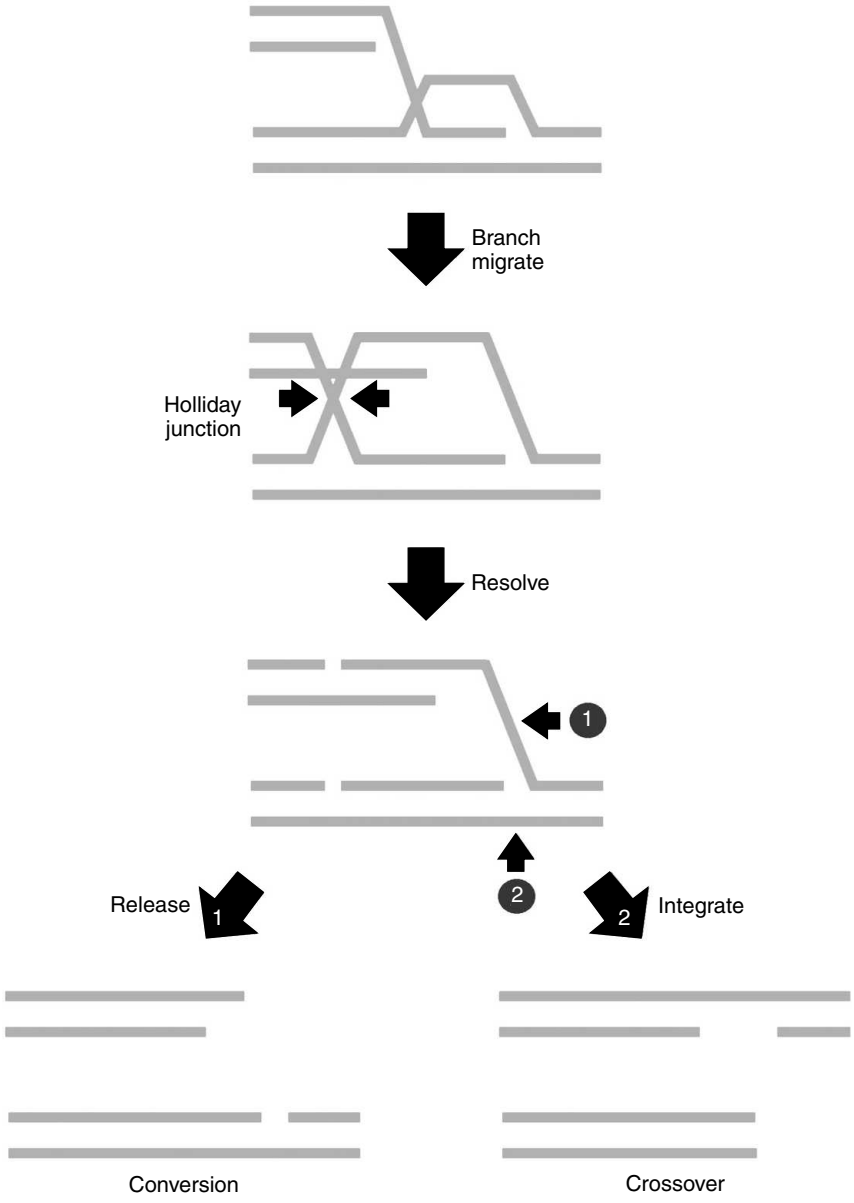

Fig. 4 Resolution of the initial heteroduplex intermediate. The initial paired structure can branch migrate to form a Holliday junction. Resolution of the Holliday junction by cleavage of the pair of strands indicated by the small arrows yields a branched structure equivalent to a replication fork. Cleavage of the branched structure at arrow 1 releases the targeting DNA, whereas cleavage at arrow 2 integrates the targeting DNA.

double-strand breaks are introduced into the target sequence. By embedding the recognition site for a rare-cutting endonuclease such as I-SceI in the chromosomal target, site-specific double-strand breaks can be introduced by transfection of an expression vector for I-SceI. When the targeting vector is included, targeted recombination can be stimulated up to 10 000-fold with the specific recombinants constituting several percent of treated cells. One or both of the chromosomal ends at the break are thought to invade the targeting duplex, extend themselves by DNA synthesis, and then disengage and pair with one another to reconstitute the duplex and eliminate the double-strand break. This mechanism, which is known as synthesis-dependent strand annealing (SDSA), provides a productive way of thinking about targeted recombination.

2.4 Stimulation of Targeted Recombination

An appreciation of the normal role HR plays in somatic cells, coupled with an understanding of the probable pathway for targeted recombination, allows one to devise rational strategies for increasing the frequency of the event. Three general approaches have been tried; altering levels of HR enzymes, introducing damage at the target site, and delivering DNA via viral infection. These approaches are not mutually exclusive, and significant improvements may require some combination of them. Below we discuss the rationale for each of those strategies and their current status.

In principle, it should be possible to increase frequencies by temporarily altering the cellular mix of HR enzymes in a way that favors targeted recombination. For example, one might try to overexpress enzymes that favor HR and inhibit those involved in competing pathways such as NHEJ. Thus far, such experiments have met with limited success. As mentioned above, inhibition of NHEJ by knocking out key components had no significant effect. Three HR enzymes – Rad51, Rad52, and Rad54 – have been tested by over expression. A fourfold overexpression of the Rad51 recombinase stimulated targeted recombination some two- to fourfold. By contrast, overexpression of Rad52 protein, which helps to load Rad51 onto single-stranded DNA, was inhibitory by about twofold. Overexpression of Rad51 and Rad52 together had little effect on targeting frequencies. Finally, overexpression of Rad54, which helps prepare the target duplex for invasion, stimulated recombination by about 10-fold (Z. Songyang, personal communication).

The positive results with Rad51 and Rad54 serve as proof of principle and encourage further experimentation along these lines, especially with enzymes in the more poorly defined, downstream portion of a pathway. The results with Rad52 raise two cautionary notes. First, it was shown that overexpression of Rad52 stimulated both intrachromosomal and extrachromosomal HR two- to fivefold. These assays measured effects on the single-strand annealing pathway of HR, which is independent of Rad51 and distinct from the likely pathway for targeted recombination. The effects of manipulating cellular enzyme levels should always be measured in targeted recombination assays. Second, stable overexpression of Rad52 was found to be toxic to cells, as was Rad51 in some cell lines. Consequently, careful adjustments in enzyme levels may be essential for optimal effects.

As mentioned above, the most dramatic effects on targeted recombination have been generated by I-SceI-mediated

cleavage of the target sequence on the chromosome. The requirement for prior modification, however, means that rare-cutting endonucleases such as I-SceI cannot be used as general tools to stimulate targeted HR, nor can restriction enzymes be used because their sites are all too common. However, zinc finger proteins can be engineered to recognize a diverse set of DNA sequences. By combining a zinc finger recognition domain with a nonspecific DNA-cleavage domain, zinc finger nucleases have been created that offer a flexible strategy for delivering site-specific double-strand breaks to the genome. In current designs, the zinc finger nuclease consists of a DNA binding domain composed of three zinc fingers linked to the nonspecific DNA-cleavage domain of FokI, a type IIS restriction enzyme. Each zinc finger recognizes a specific 3-nucleotide stretch of DNA so that the three fingers in a domain recognize a 9-nucleotide DNA segment. Because efficient DNA cleavage requires dimerization through the FokI nuclease domain, the effective recognition site is 18 nucleotides in length, long enough to be unique in mammalian genomes.

Zinc finger nucleases have been shown to stimulate intramolecular HR in 50% of plasmid molecules injected into *Xenopus* oocytes, and to cause site-specific somatic mutations in 50% of males, and germ-line mutations in 5% of males, when expressed in *Drosophila* larvae. They also stimulate targeted recombination in *Drosophila* by 100-fold, and in human cells by several 1000-fold. It should be noted that observations in *Drosophila* and in human cells indicate that high-level expression of some zinc finger nucleases can be toxic. If a broad range of zinc finger nucleases with high affinity and single-site specificity can be developed, it may be possible in the future for an investigator to select from a bank of such nucleases the one that will cleave a specific gene to stimulate localized gene targeting.

In the section on triple helix forming oligonucleotides (TFOs) in this review, we discuss two methods for using TFOs to induce HR and gene correction. First, by linking a DNA damaging agent such as psoralen to a TFO, it is possible to introduce site-specific damage to a genomic target specified by TFO binding. Introduction of a TFO into cells has been shown to stimulate up to several thousandfold intrachromosomal HR at a site containing the TFO target sequence. Second, it is possible to link a correcting segment of DNA to the TFO itself, using the binding specificity in the TFO to deliver the DNA to an adjacent target. Directed toward a plasmid target in mammalian cells, this approach stimulated homologous correction 5- to 10-fold above background levels. Improvements in design and delivery of such TFO reagents, as discussed later, will likely be required to enhance the effectiveness of this method for stimulating HR in cells.

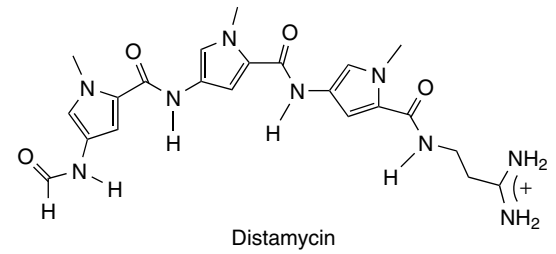
The unexplained difference in targeting frequencies between nuclear injection and mass delivery methods raises the distinct possibility that alternative ways to introduce DNA into cells might yield positive benefits. One promising approach is the delivery of DNA by viral vectors. Although retroviral vectors have been shown to target at low frequencies, adeno-associated virus (AAV), which carries a single-stranded DNA genome, has been investigated most extensively. AAV viral vectors have been shown to target chromosomal sequences at frequencies ranging from 0.01 to 1% depending on the multiplicity of infection, and on the type of alteration introduced, with insertions into the target giving generally higher frequencies than deletions. Chromosomal targets carrying an I-SceI

site, which were corrected at low frequencies by the AAV vector alone, could be targeted at about 100-fold higher frequencies in the presence of I-SceI. The relatively high frequencies of targeted recombination by AAV may reflect the nuclear delivery of a high concentration of DNA by the viral preparations, or they may relate to the single-stranded nature of AAV DNA with its hairpin-protected ends. This appears to be a promising technology although it has had relatively little exposure.

3 Polyamides

3.1 Netropsin and Distamycin

Netropsin and distamycin are natural product antibiotics consisting of two or three pyrrole (Py) rings respectively connected by amide linkages. In addition, the molecules have a positively charged propylamidine at the end designated as the tail and either formyl (distamycin) or guanidine (netropsin) groups at the head (Fig. 5). The compounds have received attention for many years and it was established some time ago that they bound AT-rich sequences in the minor groove. Both drugs have a curvature that fits quite well with the floor of the minor groove. Crystallographic studies showed that a single netropsin molecule binds in the minor groove displacing the spine of hydration. There are nonspecific ionic interactions between the positively charged head and tail groups and the negatively charged phosphates of the duplex. Hydrogen bonds between the proton donors of netropsin (the amide NH) and the DNA bases position the drug, while the actual sequence recognition results from close van der Waals contacts between atoms on the drug and adenine residues. The poor binding to GC pairs is due to steric hindrance from the 2–amino group guanine, which interferes with occupancy of the groove. The structural studies detailed the interactions that determine the affinity and specificity



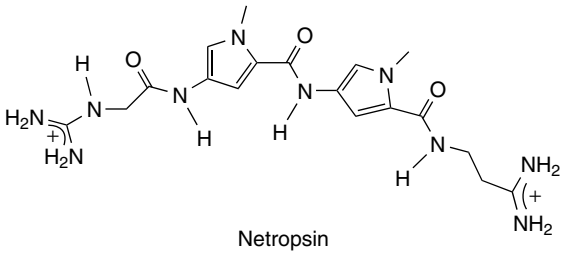


Fig. 5 The structures of distamycin and netropsin, two minor groove binding antibiotics. Each contains pyrrole residues joined by amide linkages. Note the positively charged tails and the sickle shape.

of the natural products and numerous synthetic derivatives. It was appreciated that these compounds might serve as leads for the development of sequence-specific DNA binders that could inhibit transcription of specific genes. If the suppressed genes were linked to diseases, such compounds could have pharmaceutical application. This has been a motivation for much of the work in the field.

3.2 The Development of Sequence Specific Minor Groove Ligands

A thorough discussion of the chemistry and structural properties of the numerous polyamide derivatives (sometimes called lexitropsins) is beyond the scope of this review. These features of the field have been reviewed in depth in several recent publications. We will summarize the important developments and then consider the current understanding of their biological activity and prospects for pharmacological utility.

In order to expand the binding options to GC pairs, Kopka et al. had suggested, and Lown had independently synthesized netropsin derivatives in which pyrrole was substituted with imidazole (Im). Replacement of the ring CH with N provided space for the exocyclic amine of guanine, and the N served as an acceptor of the H bond from the guanine donor. Although the new compounds recognized GC sites, they also continued to bind AT pairs, albeit with reduced affinity. These somewhat disappointing observations were rescued by one of the most important discoveries in the field. NMR studies of distamycin bound to AT sequences revealed that when the binding site contained five AT pairs, distamycin bound as an antiparallel, side-by-side, dimer, with the positively charged tails at either end (2 : 1 mode). Each drug molecule made contact with one of the duplex strands, with the N terminus at the 5′ end of the strand. In contrast, netropsin bound only in a 1 : 1 mode, because of the presence of positive charges at both ends of the molecule. The Dervan and Lown groups synthesized distamycin analogs with the pyrroles replaced by imidazole. The new compounds bound target sequences containing GC pairs, as predicted. However, further analysis by both groups determined that the optimal side-by-side arrangement for G:C binding was an imidazole:pyrrole pairing, with the imidazole interacting with the G and the pyrrole interacting with the C. Specificity was extended when the Dervan group introduced 3-hydroxypyrrole (Hp) which showed a preference for interaction with T. The Hp/Py pair recognized T:A and Py/Hp recognized A:T with discrimination greater than 10-fold depending on the orientation and target. The preference by Hp/Py for T:A is the result of shape selection by an asymmetric cleft in the minor grove and also hydrogen bonding between Hp and T. These results established pairing rules for the 2 : 1 binding motif: the pyrrole/imidazole pair (Py/Im) for C:G, Hp/Py for T:A, Py/Hp for A:T, while Py/Py is degenerate and recognizes both A:T and T:A (Fig. 6). The tails of the molecules (dimethylaminopropyl, in the compounds from the Dervan group) are placed at A:T pairs.

Additional affinity was gained when the two chains were linked (Fig. 7). Two methods of linkage have been employed. In one format, the chains are coupled via bonds between internal rings. While this did provide enhanced affinity, the more effective

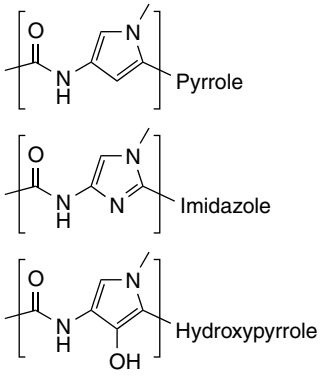

Fig. 6 The structures of the subunits of synthetic polyamide minor groove binders. When binding occurs in the 2 : 1 mode, pyrrole binds to A, T, or C, imidazole binds to G, and hydroxypyrrole binds to T. (From Goodsell, D. S. 2001, Goodsell, Sequence recognition of DNA by lexitropsins, *Curr. Med. Chem* **8**, 509–516. Reprinted with permission from Bentham Science Publishers Ltd.)

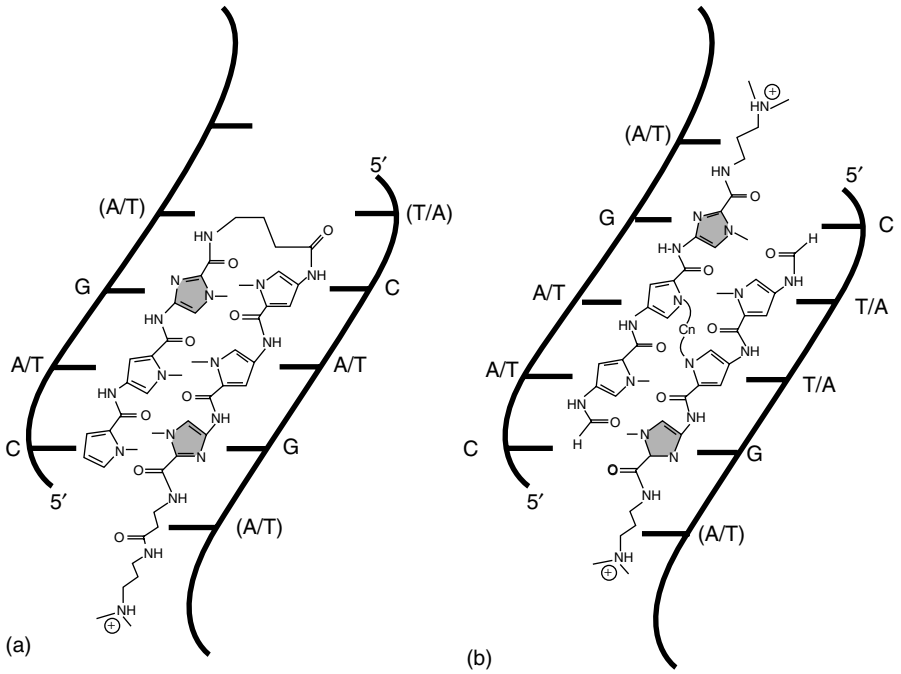

Fig. 7 (a) Hairpin and (b) ''stapled'' polyamides. Each contains 2 imidazole (stippled) residues and 4 pyrrole rings. The shifted phasing of the stapled version relative to the arrangement in the hairpin changes the target sequence. (A/T) or (T/A) base pairs at the ends of each sequence are recognized by the atoms in the linkers and tails. (Reprinted from Walker et al., 1998, PNAs **95**, 4315–4320 with permission from the National Academy of Sciences, USA.)

approach involved linkage via a head-to-tail format with the three-carbon linker, γ-aminobutyric acid. This has been employed in most subsequent syntheses. The hairpin locks the position of the subunits relative to one another, thus preventing slipped pairing schemes. This linker also binds at AT pairs, adding another

component to the recognition scheme. Although hairpin polyamides have been studied more extensively, the cross-linked polyamides continue to receive attention.

Another important development was the recognition that there was a limitation on the length of the polyamide chains. Sequence specificity and affinity were not improved beyond five rings. This was attributed to an overcurvature of the longer polyamide chain (as compared to the 3- and 4-ring compounds that match the minor groove curvature), resulting in a loss of register with the binding sites. A solution to this problem was provided by the placement of β-alanine residues after three or four polyamides. These insertions appear to act as ''springs'' to reset the phasing. When paired with each other in hairpin polyamides, or with Py, they interact with T:A and A:T pairs. When paired with Im, they can interact with C in G:C or C:G pairs, and may offer a solution to the otherwise ''difficult'' sequences. At this time, it is fair to say that considerable progress has been made in the development of the polyamide minor-grove binders. This reflects the persistent effort and ingenuity of several laboratories, the development of solid-phase methods of synthesis, and the allure of high affinity, sequence-specific ligands for ultimate pharmaceutical application.

3.3 Affinity and Specificity

The introduction of the hairpin polyamides advanced the affinity for a five-base target sequence by two orders of magnitude relative to the free three-ring compound. This brought the association constants into the nanomolar range, competitive with transcription factors. Subnanomolar affinities were reported for hairpin polyamides with four side-by-side rings binding to a six base target. These results clearly demonstrated high affinity binding by the polyamides, and suggested that they might be effective as inhibitors of transcription factor binding, and thus transcription.

The issue of specificity is, however, another matter. This question has been addressed in a number of publications from the Dervan laboratory. In one study, the binding of two eight-ring hairpin polyamides, designed to recognize sequences that contained one or two G:C pairs, was analyzed by DNAse footprinting. The constructs contained Py/Py pairs which do not distinguish A:T from T:A. Binding by one of the constructs to the specific site was subnanomolar, with two log poorer binding to two other sites with replacement of G:C by A:T or T:A. However, the other construct had a tenfold lower affinity for the specific target and only an eightfold discrimination between the specific target and the single mismatch sequence. In addition, weaker, but measurable binding (1 nM range) was seen with a double-mismatch site. In this example, both constructs bound the mismatched target with similar affinity. They differed substantially, however, in their affinity to the specific target.

Although replacement of Py/Py pairs with Hp/Py, does afford some discrimination between A:T and T:A pairs (in the range of 10 fold), it does so at the expense of affinity. Thus, the more effective binders are the compounds with no discrimination between A:T and T:A, and perhaps because of this, the Hp subunit has received little use in the recent work from the Dervan laboratory.

Binding to a single site in the human genome would require specific recognition of about 16 contiguous base pairs. In

the initial efforts to increase the target specificity of the polyamides the Dervan group constructed six- or eight-ring polyamides with internal β-alanine linkers. These bound via a ''slipped pairing'' mode in which there was a partial overlap of the individual polyamide chains in minor groove, with extension of the remaining unpaired chains along the target sequence. These did bind sequences as long as 16 bases. However, binding to mismatch sites was also observed with affinities relatively close (5–20-fold) to the perfect match targets. The Laemmli group has also prepared linked hairpin polyamides designed to bind insect telomeric repeat sequences. While the dimer bound with 10- to 20-fold higher affinity than the unlinked monomer, at higher concentrations it also bound almost all the sequences in the probe (termed ''coating'' by the Laemmli group). One unavoidable difficulty with all these studies is that analyses of specificity are limited by the sequences chosen for the binding experiments. Obviously, the array of potential binding sites in the genome cannot be represented with this strategy. However, even within this limitation it is apparent from visual inspection of the DNAse footprints from virtually all of the polyamide literature that binding occurs to many sites other than those of specific interest (Fig. 8).

A recent publication highlights some of these points. Colon cancer cells in culture were incubated with a polyamide designed to inhibit binding of the LEF-1 transcription factor to an eight-base

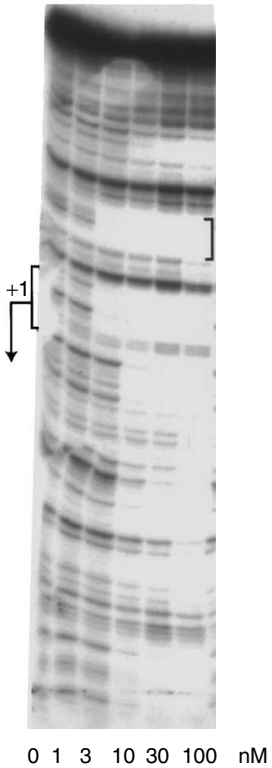

Fig. 8 DNAse footprint analysis of polyamide binding to the upstream promoter region of the *Xenopus TyrD* tRNA gene. A ^{32}P labeled restriction fragment was incubated with the polyamide at the indicated concentrations and then digested with DNAse. Protected regions are not digested and appear as blanks in the pattern. The brackets indicate the regions the polyamide was designed to protect. The arrow denotes the transcription start site. (From McBryant et al. (1999) *J. Mol. Biol.* **286**, 973–981. Reprinted with permission by Elsevier Science.)

sequence in the promoter of the cyclin D1 gene (CD1). The authors were careful to demonstrate nuclear localization of the polyamide. This was an important issue as another study suggested limitations in nuclear uptake of these compounds. The effect on message expression was examined by hybridization array analysis. Although the levels of a number of messages were affected, it was noteworthy that the levels of the targeted CD1 gene were unchanged. A computer search of the promoters of the 11 000 genes represented on the hybridization array yielded 37 380 candidate binding sites for the anti-CD1 polyamide.

3.4 Biological Applications

Early in the development of polyamides they were seen as having the potential to become rationally designed transcriptional inhibitors. Important support for this concept was provided by the demonstration that a hairpin polyamide could suppress transcription of a *Xenopus* 5S RNA gene. The compound was designed to bind a specific sequence in the binding site of the 5S RNA gene transcription factor, TFIIIA. The polyamide reduced 5S transcription in both cell extracts and live cells. In an experiment with therapeutic implications, combinations of appropriately designed polyamides were shown to inhibit HIV transcription in a cell-free assay, and to block HIV replication in peripheral blood lymphocytes. Since then there have been several studies describing biological applications of polyamides. They can inhibit transcription factor binding, and transcription *in vitro*. Most, but not all, sites on nucleosomal DNA are bound by polyamides, which block the progress of RNA polymerase through nucleosomes, apparently by inhibiting repositioning of nucleosomes during transcription. In an interesting new direction, polyamides were linked to transcriptional activation domain proteins. The polyamides provided sequence-specific DNA binding and the conjugates functioned as artificial transcription factors in transcription assays *in vitro*.

Perhaps the most spectacular publications are from Laemmli and colleagues, who synthesized polyamides targeted at the AT-rich, satellite scaffolding–associated regions of Drosophila. The satellites are found in condensed heterochromatin, and genes near these regions are silenced because of the chromatin structure. The satellite sequences are bound by the MATH (for multi-AT hooks) protein that interacts with AT tracts through minor groove contacts. The experimental rationale was based on the expectation that the polyamides would interfere with MATH dependent heterochromatin condensation. Treatment of nuclei resulted in extensive chromatin unfolding and selective staining of polytene chromosomes in the expected satellite region. Even more remarkable was the result of feeding the compounds to flies. The flies normally showed a strong variegation in eye (mottled red/white) color due to a juxtaposition of the *white* gene adjacent to the heterochromatin satellite region (resulting in variable silencing of the gene for the red color). Depending on the polyamide and the intended target, the flies showed an increase in the red color phenotype. This was interpreted as due to an opening of the chromatin resulting in relief of the suppression of the red color gene. Additional experiments with a different polyamide targeted to a different satellite at another locus also had pronounced effects on gene expression.

The results of both series of experiments suggest that extensive chromatin remodeling could result from polyamide treatment. While the effects on transcription were indirect, these results argued that polyamides could reach nuclei of living cells in whole organisms, with remarkable consequences for chromosome structure and gene expression.

Although considerable effort and intelligence has been brought to the development of polyamides, there are serious questions on the likelihood of their becoming successful drugs. Concerns about target specificity and effects on chromatin structure will have to be addressed before pharmacological applications can be considered.

4
Triple Helix–Forming Oligonucleotides

4.1
Triple Helical DNA

The DNA triple helix was discovered more than forty years ago and has been studied persistently ever since. The most stable triplexes form on polypurine:polypyrimidine tracts, which are abundant in the human genome, particularly in promoters and introns. The third strand of nucleic acid, which may consist of purines or pyrimidines (depending on the target sequence), lies in the major groove of an intact duplex. The complex is stabilized by two "Hoogsteen" hydrogen bonds between third strand bases and the bases in the purine strand of the duplex. These are formed without interfering with the hydrogen bonds between the bases of the duplex strands. Pyrimidine motif (Y.R:Y) third strands bind in a direction parallel to the purine strand in the duplex, with canonical base triplets of T.A:T and C.G:C (by convention the first base of the indicated base pair is the purine). Purine motif (R.R:Y) third strands bind antiparallel to the purine strand, with base triplets of A.A:T and G.G:C. Typically, the purine motif is used for G:C rich targets, and the pyrimidine motif for A:T rich targets (Fig. 9).

For most of the three decades following the initial discovery, triplex research was largely the province of DNA structural and physical chemists until methods were developed for automated, solid phase–based, oligonucleotide synthesis. The demonstration that synthetic oligonucleotides could form stable triplexes led to the explicit suggestion that TFOs could be developed as sequence-specific targeting reagents in living cells. Although largely conducted in the absence of biological assays, the many years of biochemical and biophysical research did define a number of obstacles that had to be, and still must be, overcome in order for TFOs to become a legitimate option for gene targeting. Consideration of biological applications raises four major issues: the activity, under physiologically relevant conditions, of TFOs directed against the classical homopurine:homopyrimidine targets in purified DNA; the activity against more general sequences; the activity against chromosomal targets, in the context of mammalian chromatin structure; and, the molecular consequences of successful triplex formation, that is, what happens after binding. Solutions to the first two have been, and will continue to be addressed by developments in oligonucleotide chemistry, while the third and fourth are the subject of active research from more biochemical and biological perspectives.

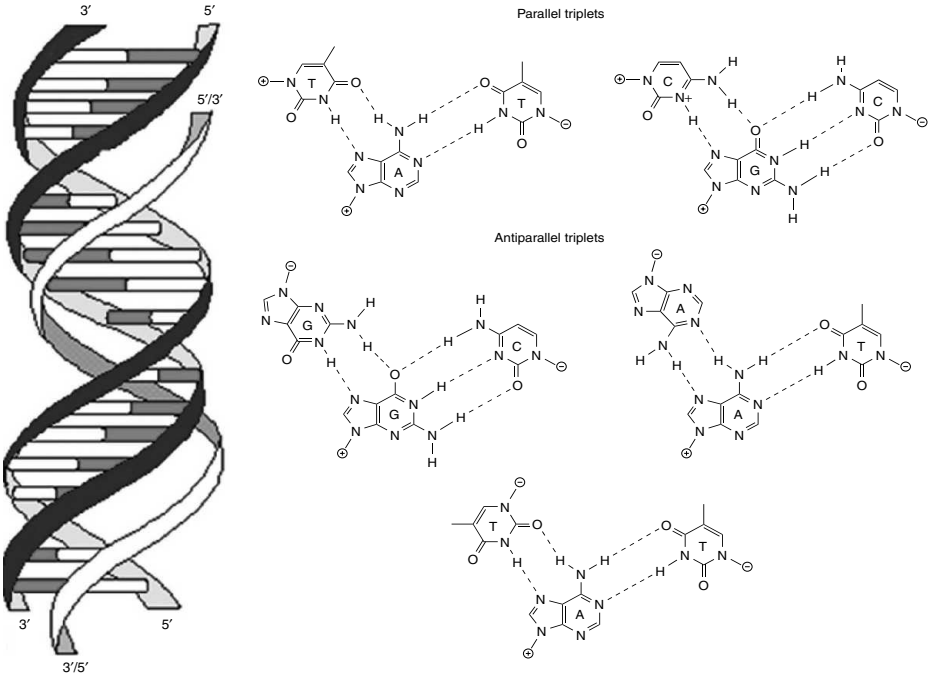

Fig. 9 The structure of the DNA triple helix. A third strand of nucleic acid lies in the major groove of an intact duplex. The target sequence consists of purines on one strand and pyrimidines on the other. Specificity and stability are provided by Hoogsteen hydrogen bonding between the bases in the third strand and the purine bases in the duplex. These hydrogen bonds do not perturb the Watson–Crick bonds of the duplex strands. Third strand orientation relative to the purine duplex strand is a function of the third strand composition – those in the pyrimidine motif bind with the same polarity as the duplex purine strand (''parallel''), while purine motif third strands bind in the opposite polarity (antiparallel). In pyrimidine, third strands T bind to A:T pairs, and C to G:C pairs. In purine, third strands G bind to G:C, A to A:T, and T can bind to A:T pairs. Note that the TA:T pairs in the two different motifs are not identical.

4.2 Triplex Formation under Physiological Conditions

Triplex formation is an inherent property of DNA without the requirement for enzymes or proteins. Nonetheless, the probability of complex formation is affected by fundamental biophysical considerations, which are further complicated by the constraints of a physiological environment. A negatively charged third strand must approach and bind a doubly negatively charged duplex, via a zipper type mechanism following an initial nucleation event involving three to five bases. In the test tube charge repulsion can be reduced by use of levels of Mg^{++} (5–10 mM) that are much higher than likely to be available as the free ion in cells. Pyrimidine motif triplexes do not form at physiological pH because of the requirement for cytosine protonation that occurs at relatively acidic pH ($pK_a = 4.5$). This is necessary for one of the hydrogen bonds (Fig. 9), and the resultant positive charge also

makes an important contribution to triplex stability. Purine motif third strands (which are G rich) can form G-tetrad structures in physiological levels of K^+, inhibiting triplex formation. Finally, conformational changes are required by both the third strand and the duplex target. All these factors contribute to the much slower kinetics of triplex formation relative to duplex formation, and reduce triplex stability (most triplexes, even under optimal conditions *in vitro*, are less stable than the underlying duplex).

4.3 Oligonucleotide Modifications Improve TFO Activity

Certain base and sugar modifications improve TFO activity under physiologically relevant conditions. For example, 5-methylcytosine partially alleviates the pH restriction of TFOs in the pyrimidine motif, due to the contribution of the methyl group to base stacking and/or the exclusion of water molecules from the major groove.

RNA third strands form more stable pyrimidine motif triplexes than the corresponding DNA strands, and that observation led to the use of RNA analog sugar residues such as 2′-*O*-Methyl (2′-OMe) (Fig. 10). Other analogs, such as the 2′, 4′ bridged ribose (Locked Nucleic Acid, LNA, or Bridged Nucleic Acid, BNA) also improve triplex stability. These modifications stabilize the C-3′ endo configuration of the sugar. This has the salutary effect of preorganizing the third strand in a conformation that is compatible with triplex formation, while also imposing minimal distortion on the underlying duplex. Many other modifications have been considered. These include intercalators linked to TFOs and the base analog propynyl-deoxyuridine, both of which stabilize triplexes. The Mg^{++} dependence of pyrimidine motif TFOs has also been reduced by modifications to the backbone, such as replacement of the phosphate linkage, or a bridging oxygen with a nitrogen. Substitution of a nonbridging oxygen in the backbone with a charged amine reduces G-tetrad formation by purine TFOs in physiological K^+, making more oligonucleotide available for triplex formation and reducing the charge repulsion.

A positive charge and an RNA-like sugar conformation have been combined in the 2′-*O*-(2-aminoethyl) (AE) ribose derivatives of Cuenoud and colleagues. TFOs carrying these substitutions can form triplexes at rates over 1000-fold faster than corresponding deoxy third strands. The stability of the resultant complex at physiological pH and low Mg^{++} concentration is also enhanced. NMR analysis indicates a specific interaction between the positively charged amines (at physiological pH) and phosphate groups in the purine strand of the duplex.

Although the biochemical data indicate that these modifications improve TFO binding, few have been tested in biological assays. In the following section, we will

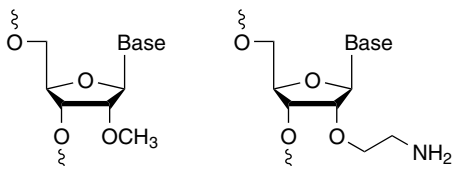

Fig. 10 The structure of modified sugars incorporated in triple helix forming oligonucleotides, 2′-O-methyl (2′-OMe) and 2′-O-aminoethyl (2′-AE).

discuss the biological activity of TFOs carrying some of these substitutions.

4.4 Activity of TFOs *In Vivo*

Any effort to develop TFO for gene targeting in living cells must be cognizant of the potential restriction to triplex formation by eukaryotic chromatin structure. It has been shown in biochemical experiments that target sequences in nucleosomes are poor substrates for triplex formation. However, chromatin structure is dynamic *in vivo*, and there are recent indications that manipulation of the biology of the cell can influence targeting efficiency (see below).

In the early biological studies, TFOs were envisioned as tools to inhibit gene expression by blocking transcription initiation or elongation (the antigene strategy). Triplex formation within promoter sites can block transcription factor access, and inhibit gene activation *in vitro*. Promoters of active genes are often nucleosome free or have nucleosomes whose interaction with the DNA has been relaxed by remodeling or histone modification. Results from a number of investigators suggest that TFOs designed to bind specific promoters can decrease expression of the targeted gene in mammalian cells. The results of these and similar studies suggest that TFOs can find chromosomal targets and produce a measurable biological endpoint. However, the evidence for target interaction is necessarily inferential and there is no direct demonstration of TFO binding at the target site. Furthermore, as is well documented in the antisense literature, oligonucleotides can have multiple effects on cells and transcript levels, via mechanisms unrelated to their original design.

In an alternative approach, TFOs have been used for genome modification, resulting in a change in target sequence. This has the advantage of introducing permanent changes in the target sequence, which simplifies interpretation of the experiments. Two strategies have been employed: in the first the TFO is linked to a DNA reactive compound, while in the second the binding of the TFO is sufficient to elicit a response.

4.5 TFOs Linked to DNA Reactive Compounds

TFOs linked to DNA reactive compounds have been used to introduce DNA adducts at specific target sites. TFOs conjugated to cleavage and alkylating reagents have been described, although these reagents have been largely restricted to biochemical experiments. The most useful, and most frequently used reagent is psoralen, a DNA cross-linker requiring photoactivation by long wave ultraviolet light. In the initial biological experiments, purine motif TFOs conjugated to psoralen were used to target cross-links to a specific site on mutation reporter plasmids or phage *in vitro*. Passage of the modified vectors through host cells resulted in mutagenesis of the target site. Psoralen-conjugated TFOs that transfected into cells were shown to induce base pair-specific mutations within a *supF* mutation reporter gene in a shuttle vector plasmid either cotransfected or previously transfected into cells. These results demonstrated intracellular targeting by a TFO, and also demonstrated that the mutagenesis assay could be used to relate the affinity of the TFO to the biological activity.

The shuttle vector experiments were followed by the demonstration of targeted mutagenesis of a chromosomal site by

a psoralen-linked pyrimidine TFO containing 2′-OMe sugars and a pyrene intercalator. The target sequence was in the endogenous hamster *HPRT* (hypoxanthine phosphoribosyltransferase) gene. Cells with inactivating mutations in *HPRT* can be quantitatively identified in a simple and unambiguous selection procedure. TFOs with uniform 2′-OMe substitutions were inactive, but those with the pyrene intercalator showed *HPRT* knockout activity at frequencies in the range of 10^{-4} to 10^{-3}. Sequence analysis of the mutant clones confirmed the localization of mutations to the target region. More recently, psoralen-linked TFOs containing several 2′-AE-residues as well as 2′-OMe substitutions have been prepared. These mixed substitution TFOs form triplexes at lower levels of Mg^{++} than required for the TFOs with only the 2′-OMe residues. Thermal melting experiments showed that the AE triplexes were more stable than the 2′-OMe only triplexes, and notably, were more stable than the underlying duplex at physiological pH. The AE TFOs were much more active in the *HPRT* knockout assay than the 2′-OMe TFOs. As discussed above, the enhanced biochemical and biological properties are due to the positive charge of the amine group. Recently it has been shown that psoralen-TFOs, carrying optimal levels of AE substitutions, can introduce mutations at the HPRT target site at frequencies in the range of 5%. This is sufficiently high to allow identification of cell clones with targeted mutations in direct screens without a requirement for selection.

Access to chromatin targets has been considered in studies with nuclei and in permeabilized cells and has been shown for psoralen-linked TFOs, as well as for a TFO alkylator conjugate. In these experiments, the frequency of cross-linking served as a measure of TFO binding at the time of photoactivation. Targeting activity was greatest in cells in which the target region was undergoing active transcription prior to permeabilization. In recent work, we have found that the frequency of targeted cross-links in living cells (and the resultant mutagenesis) is greatest in S-phase cells.

These results argue that transcription and replication can influence target access. However, the relationship between specific chromatin structures and target access remains to be determined.

4.6
Triplex Formation, by itself, can Promote Mutagenesis

Triplex structures are recognized by DNA repair proteins such as XPA/RPA. The possibility that this recognition could lead to mutagenesis was raised in experiments in cultured mammalian cells cotransfected with a plasmid containing a *supF* reporter gene with an embedded triplex target site and a purine motif TFO, designed to bind the target. Plasmids with mutations in the *supF* gene were recovered. These included deletions and point mutations distributed throughout the gene, and resembled those recovered from experiments with nicked plasmids. Mutagenesis was independent of psoralen, but did require functional DNA repair and transcription coupled repair functions. It seems likely that some triplex structures are recognized as lesions and trigger DNA repair with an error-prone outcome, as well as other events associated with DNA metabolism (see below).

Chromosomal targets in both cultured cells and transgenic mice have been mutagenized by treatment of cells or mice

with purine motif TFOs. Unconjugated purine motif TFOs were employed, and the mutations included frameshifts (in the homopolymer runs of the target sequence) and distributed point mutations. In the mouse experiment, all tissues tested showed TFO-induced mutagenesis except the brain, which had no mutagenesis over background, consistent with TFOs being unable to cross the blood–brain barrier. The mutations were consistent with error-prone filling of gaps or slipped pairing during gap filling. Thus TFO targeting is possible in whole animals.

4.7 Triplex-induced Recombination and Gene Correction

The suggestion that triplexes would be recognized as a substrate for DNA repair prompted the notion that they might also trigger recombination. Experiments with a TFO and shuttle vector plasmid carrying two (different) mutant copies of the *supF* gene with the TFO target site between them demonstrated that triplex formation, with or without psoralen cross-linking, could induce recombination to produce a functional *supF* gene to psoralen. Gene correction was dependent on a functional XPA protein, a DNA damage–recognition protein and a component of the nucleotide excision repair machinery.

This approach has been extended to a chromosomal target in mouse fibroblasts. This was prepared by integration into a single chromosomal location of a construct containing a triplex target sequence with different mutant *thymidine kinase* (*TK*) genes placed on either side. When the appropriate TFOs were microinjected into the nuclei of the cells, the yield of recombinants was 1 to 2%, more than 1000-fold over background. Analysis of the recombinant clones revealed that all the recombination events involved gene conversion. Similar studies using TFOs to stimulate recombination have also been described using a locus in CHO cells containing duplicated *APRT* genes as a target.

The observation that third strand binding could provoke DNA repair and stimulate recombination led to the development of a strategy to mediate targeted gene conversion. In this protocol, a TFO was linked to a short DNA fragment homologous to the target site (except for the base pair to be corrected). The conception of the approach is that the TFO domain mediates site-specific binding to target the molecule to the desired gene. This binding would also trigger repair to initiate recombination or gene conversion with the ''tethered'' donor sequence. This idea was tested with an oligomer containing a 40-mer donor element and a 30-mer TFO domain. Correction of a single base pair mutation in the *supF* reporter gene in a shuttle vector plasmid in mammalian cells was shown. *In vitro* studies in human cell-free extracts revealed a requirement for XPA and Rad51 in the recombination pathway.

4.8 Expansion of the Triplex Binding Code

Although research on the biological applications of TFOs must be considered to be in the early stages, it does appear that three of the important issues raised above have been addressed: it is possible to synthesize TFOs that are functional *in vivo*; chromosomal targets are accessible, and accessibility can be modulated by manipulating the cell biology; TFOs can be used to target mutagenesis and recombination. Thus, although there is a great deal to be done to extend these conclusions, expansion of

target options to mixed purine/pyrimidine sequences would appear to be the most important challenge facing the field. It is likely that solutions will come from synthetic chemistry via novel base analogs. Although there have been some interesting directions identified in the effort to expand the triplex binding code, it is fair to say that at this time there are no analogs that permit binding to general sequences. This remains an area of opportunity.

5
Mutation Repair by Small DNA Fragments

A seemingly attractive approach to introducing defined sequence changes into chromosomal loci would be based on conventional DNA fragments, homologous to the target region except for the intended change. The strategy is based on the notion that heteroduplex formation between the target and the donor sequence would be resolved, at least some of the time, in the experimentalist's favor. The method would take advantage of the four base recognition code, and relative ease and low cost of preparation of the correcting reagents. The formation of the critical heteroduplex would result from the action of the recombination apparatus in the host cells, or, (perhaps in the case of single-strand fragments) as a result of transient exposure of single-strand regions during replication, transcription, or repair. That such an approach might work is supported by the early demonstration of ''marker rescue'' by Edgall and Hutchison, in *E. coli*. Measurable correcting activity of single-strand oligonucleotides against a chromosomal target in yeast, an extrachromosomal target in mammalian cells, and, recently, the chromosomal *HPRT* gene in mammalian cells have also been reported. The frequency of correction in all these reports was too low to have practical utility. Short double-strand fragments were also shown to have low correcting activity in mammalian cells. In a recent work, oligonucleotides have been used to manipulate chromosomal gene sequences in *E. coli* at frequencies high enough to have practical utility. The much higher frequencies in the bacterial host may reflect fundamental differences in the exposure of single-strand regions in *E. coli* versus mammalian cells.

5.1
Small Fragment Homologous Replacement

Gruenert and colleagues have developed an approach based on double-strand fragments approximately 500-bp long (termed *small fragment homologous replacement, SFHR*). They have been largely concerned with the correction of mutations in the cystic fibrosis transmembrane conductance regulator (CFTR). They have introduced fragments designed to correct the common ΔF508 mutation (a deletion of three bases) and presented PCR-based evidence for conversion at the level of the chromosome and mRNA. They have argued that the conversion frequency was in the range of 1 to 10% of treated cells. Recently, this approach has been extended to the correction of a mutation in the dystrophin gene in mouse cells. Although evidence for correction was presented, expression of wild-type distrophin was not observed. While the SFHR method may prove useful, it has received attention from few laboratories and no mechanistic studies have been performed. One of the limitations in developing the methodology has been the focus on disease genes as targets. Although of obvious interest, they

do not lend themselves to straightforward quantitative measurement of correction events.

5.2 Chimeric Oligonucleotides

A review of oligonucleotide and DNA fragment–based gene correction technologies would not be complete without mention of chimeric oligonucleotides and the claims for their activity by Kmiec and coworkers. In the original description, these were foldback molecules containing a DNA double-strand region that contained a "correction" base pair flanked by a stretch of DNA: 2′-OMe hybrid (RNA–DNA oligonucleotide, RDO). Treatment of cells carrying a β-globin sickle-cell mutation with a "wild-type" chimeric oligonucleotide was reported to result in very high levels of correction (30–50%) after 6 h of treatment. However, there has been widespread failure to reproduce this and other claims from this group, and it is not clear that the original report is credible.

6 Peptide Nucleic Acids

Peptide nucleic acids (PNAs) are DNA analogs consisting of nucleobases attached to a peptide backbone of *N*-(2-aminoethyl)glycine residues (Fig. 11). The spacing of the bases along the backbone maintains the register relative to canonical DNA-permitting base pairing between PNA strands and DNA or RNA strands. The replacement of the phosphate backbone by a neutral linkage greatly reduces the charge repulsion between PNA and DNA or RNA strands. Thus, very stable PNA:DNA or PNA:RNA hybrids are formed. They can also form four stranded complexes with polypurine:polypyrimidine DNA duplex targets. Binding to duplex DNA involves triplex formation with one strand of PNA acting as a third strand paired via Hoogsteen hydrogen bonds to the purine strand of the duplex (as in a conventional triplex), while another PNA

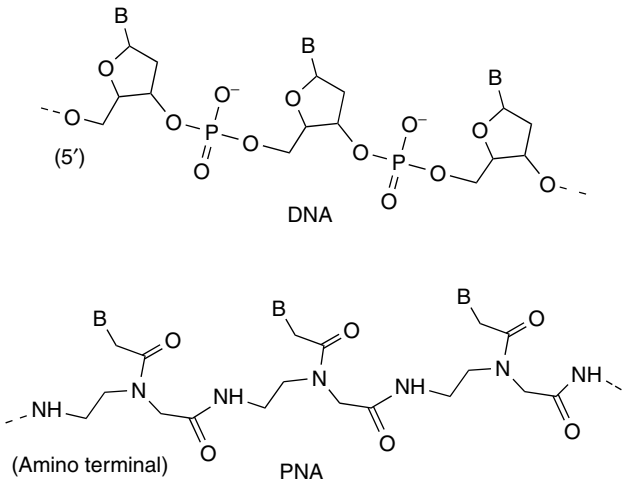

Fig. 11 The structure of a peptide nucleic acid backbone (PNA) as compared to DNA. (Reprinted from with permission from Elsevier Science).

strand forms Watson–Crick pairs with the same purine strand (PNAPNA:DNA). The latter interaction occurs by way of what has been termed *strand invasion* in which the duplex DNA partner is eventually displaced by the PNA strand. This results in a very stable "clamp" structure with the pyrimidine strand of the duplex looped out. Linkage of the two PNA strands to form bis-PNAs improves binding by reducing entropic barriers. Although PNAs bind with high affinity under optimal conditions, it is important to note that binding is dependent on breathing of the duplex. At physiological salt concentrations, binding is almost completely suppressed, suggesting that strand capture, rather than strand invasion, may be a better description of the process of complex formation between PNAs and duplex targets. Basic peptides have been attached to bis-PNAs in order to accelerate binding to linear duplex DNA. Recently, this approach was shown to partially ameliorate the restriction on binding by salt concentrations of 100 mM KCl.

The limitation on binding activity by physiological salt concentrations would appear to mitigate against gene targeting by PNAs *in vivo*. However, reports from the Glazer laboratory suggest that at least some binding occurs at chromosomal targets *in vivo*. PNAs were designed to form clamp complexes with polypurine sites in a *supF* gene, which was integrated into the genome of murine cells. Treatment of the cells with the PNAs resulted in mutagenesis of the *supF* gene, at frequencies 10-fold above the background. The mutations were single-base insertions and deletions, as well as single-base substitutions, within a run of guanines. The mutations could be rationalized by a replication slippage model. In another experiment, PNAs were targeted to polypurine sites upstream of the transcription start site for the human Gγ-globin gene. Treatment of K562 cells, which have low levels of γ-globin message, resulted in the enhanced expression of the gene from start sites at the PNA binding site as well as from the native promoter. The interpretation of both experiments is that the PNA clamp structure can form *in vivo* on a chromosomal target and the resultant "lesion" can stimulate error-prone DNA repair synthesis and/or transcription on the opened template strand. This structure also stimulated the recombination in cell-free extracts.

7 Summary

At the outset of this review, we noted that targeting reagents could be classified according to their approach to target recognition via the major or minor groove, or single strand. This is a useful way of thinking about the problem of sequence recognition and discrimination. At the end of the review, it is appropriate to consider the problem from another perspective and ask which strategies work in terms of selective sequence recognition. The simplest answer is that the successful approaches are those with the benefit of selection, during evolution, such as HR, or in the laboratory such as the zinc finger proteins reviewed elsewhere in this series. In contrast, those approaches based on chemistry supported by molecular modeling have been less effective. Thus, the considerable efforts to construct base analogs that expand the triplex binding code, or polyamides with high sequence selectivity, have had limited success. To a certain extent, this is the result of gaps in our understanding of the molecular architecture

of target sequences under physiological conditions. Although molecular models are often compelling and promise success, the results often expose the limitations of the models rather than confirm the efficacy of the constructions. It may be that substantial improvements of reagents, based on chemistry, will require the application of combinatorial, or quasi-combinatorial, strategies in which effective solutions are derived by evolution in the laboratory, rather than by reliance on models.

Keywords

ABCA1
A membrane lipid–transport protein involved in cholesterol and/or phospholipid efflux from cells. Its action is necessary for the extracellular assembly of lipoprotein particles.

Adhesion Molecules
These are proteins on the luminal surface of endothelial cells, bind to counter receptors on the membrane of leukocytes, and enable the leukocytes to attach tightly to the surface of the endothelial cells.

Angina Pectoris
Chest pain caused by reduced blood flow to the heart due to the blockage of coronary arteries by blood clots.

Angiogenesis
The process of formation of new blood vessels.

Angioplasty
An intervention to increase blood flow in a clogged artery. It involves insertion of a balloon catheter into the blocked artery and subsequent inflation of the balloon to break open or squash the atherosclerotic lesion and/or blood clot that is reducing blood flow.

Apical Membrane
In polarized cells (e.g. hepatocytes in the liver, enterocytes in the intestine), the membrane exposed to the outside world; in the hepatocytes, the bile canalicular membrane; in enterocytes, the membrane exposed to the intestinal lumen.

ApoA1
An apolipoprotein principally associated with HDL, an activator of lecithin cholesterol: acyltransferase. It interacts with the cells to mediate delivery of cholesterol ester from HDL particles.

ApoB100
An apolipoprotein associated with VLDL and LDL particles, synthesized in the liver, a ligand for the LDL receptor.

ApoB48
An apolipoprotein associated with chylomicrons, synthesized in the intestine; it is a truncated form of apoB100 and does not bind to the LDL receptor.

ApoE
An apolipoprotein principally associated with VLDL and chylomicrons, is responsible for the receptor-mediated clearance of IDL and chylomicron remnants, is a ligand for most members of the LDL-receptor superfamily. The apoE4 isoform is associated with increased risk of Alzheimer's Disease.

Apolipoproteins
The protein components of plasma lipoproteins.

Apoptosis
The programmed cell death of a cell or cellular suicide. It is a defined molecular pathway where proteolytic enzymes are activated to destroy key cellular proteins.

Atherosclerosis
An inflammatory disease in the arterial wall leading to the accumulation of cellular outgrowths that can become unstable, break off, and cause the formation of blood clots.

Basolateral Membrane
In polarized cells, the membrane exposed to the inside world; in hepatocytes, the sinusoidal membrane, which is exposed to venous circulation, in enterocytes, the basolateral membrane, which is exposed to the lymphatics and venous circulation.

Bile Acids
Detergent-like molecules formed from cholesterol. They are secreted by the liver and together with cholesterol and phospholipids, form bile. Bile forms micelles that emulsify lipids in the intestinal lumen aiding in their absorption.

Chemokines
A category of cytokines that function specifically to chemically attract leukocytes to sites of inflammation.

Chylomicron Remnants
Chylomicron particles that have been depleted of triacylglycerol after the lipoprotein lipase–mediated hydrolysis of their triacylglycerols.

Chylomicrons
Lipoprotein particles produced in the intestine to package and secrete dietary lipids. Chylomicrons are secreted into the mesenteric lymph.

Cytokines
Cell regulatory proteins secreted by many cell types that are key factors in the initiation and control of inflammation.

Familial Hypercholesterolemia
Elevation in LDL cholesterol due to mutations at the LDL-receptor locus.

Familial Hypoalphalipoproteinemia
Deficiency in HDL cholesterol due to mutations at the ABCA1 locus.

Fatty Streak
Earliest stage in the development of an atherosclerotic lesion. It consists of aggregates of macrophage-derived foam cells and lymphocytes that form underneath the endothelial lining of an artery.

Fibrous Cap
A thin layer of smooth muscle cells and connective tissue that encapsulates areas of dead cells and lipid in a developing atherosclerotic lesion. If the fibrous cap is too thin, it can break and enable formation of blood clots that can clog arteries.

Foam Cells
Primarily macrophages that have taken up large numbers of modified lipoprotein particles and have stored the excess lipid in non membrane bound cholesteryl-ester droplets and in increased numbers of secondary lysosomes.

Gallstones
Large crystals, usually composed of cholesterol, that form in the biliary tract and/or gall bladder when cholesterol levels in bile are too high relative to phospholipid and bile acids.

Growth Factors
Secreted by many cell types and by binding to specific receptors on the plasma membrane of adjacent cells, are potent regulators of cellular functions, including proliferation, migration, differentiation, and survival/apoptosis.

HDL
High-density lipoprotein, carries about 20% of plasma cholesterol. Its levels negatively correlate with risk of coronary heart disease. Is thought to mediate ''reverse cholesterol transport.''

Hemorrhage
Bleeding into a tissue. In atherosclerotic lesions, it occurs when the lesion forms fissures or ruptures and is an indication that the lesion is unstable.

IDL
An intermediate density lipoprotein, also called ''VLDL remnant.'' It is the VLDL particle that has been depleted of triacylglycerol through the action of lipoprotein lipase.

Intima
The inner layer of a muscular artery. It is the space immediately behind the endothelium where atherosclerotic lesions develop. In normal, nondiseased human arteries, there is a diffuse thickening of the intima that contains connective tissue and sparse numbers of macrophages and smooth muscle cells.

Ischemia
The inadequate perfusion of a tissue with blood leading to the reduced availability of oxygen and nutrients in the tissue.

LDL
Low-density lipoprotein carries approximately two-thirds of plasma cholesterol. Its levels are positively correlated with the risk of coronary heart disease and is formed in the circulation from the catabolism of VLDL.

LDL Receptor
Expressed in most tissues and is mainly necessary for normal clearance of LDL from the bloodstream.

Lipoprotein Lipase
Catalyzes the hydrolysis of VLDL and LDL triacylglycerols to free fatty acids and glycerol, and is present on the luminal surface of the capillary endothelium.

Lipoproteins
Particles that transport lipids in the bloodstream.

Media
The middle layer of a muscular artery that contains concentric rings of smooth muscle cells oriented perpendicular to blood flow. The orientation allows the contraction of the smooth muscle cells to constrict the artery. Atherosclerotic lesions do not initially form in the media but can expand and replace the media in very advanced stages of the disease.

Myocardial Infarction
The necrotic death of heart tissue due to a sudden blockage of blood flow to the affected tissue. It most frequently occurs following the formation of a blood clot on top of an atherosclerotic lesion that has ruptured in a main coronary artery.

Necrotic Zones
Areas within an atherosclerotic lesion that contain dead cells and debris, and lipid droplets formed from dead foam cells and aggregated lipoproteins. The expansion of necrotic zones into a *necrotic core* can make the lesion unstable and at risk of rupture.

Neovascularization
The formation of new, small blood vessels within an advanced atherosclerotic lesion. Neovessels are often formed deep in the lesion where there is limited diffusion of oxygen and nutrients, and can be a conduit for bringing more leukocytes into the advanced lesions.

Restenosis
The process of reformation of an arterial lesion that reduces blood flow following an intervention procedure such as angioplasty. A restenotic lesion is not the same as an atherosclerotic lesion as it forms primarily because of the migration and proliferation of smooth muscle cells following injury to the artery caused by the intervention procedure. It occurs in up to 40% of people who have angioplasty to increase blood flow to the heart.

Scavenger Receptors
Bind to a wide range of molecules, including modified forms of LDL. Are involved in the accumulation of cholesterol in macrophages and smooth muscle cells in the arterial wall.

Statins
Drugs that inhibit the synthesis of cholesterol. They increase the abundance of the LDL receptor and thus reduce plasma LDL levels.

Tangier Disease
A severe HDL deficiency syndrome caused by homozygous mutations at the ABCA1 locus.

Thrombosis
The formation of blood clots. A thrombus consists of variable numbers of aggregated platelets, red blood cells, and fibrin. In the heart, brain, or peripheral blood vessels, it can be an *occlusive thrombus* that blocks blood flow, or a smaller *mural thrombus* that is attached to an atherosclerotic lesion and does not block blood flow.

Vasospasm
The transient constriction of a blood vessel. Depending on the extent of constriction, blood flow can be reduced leading to tissue ischemia.

VLDL
Very low-density lipoprotein, a triacylglycerol-rich lipoprotein assembled in the endoplasmic reticulum and Golgi of hepatocytes and then secreted into the bloodstream. While in the circulation, its triacylglycerol core is depleted through the action of lipoprotein lipase and it gives rise to low-density lipoprotein.

1 Overview of Gene Therapy

Gene therapy refers to the expression of a recombinant gene in a patient. The recombinant gene can be delivered to the patient directly or it can be incorporated into cells *in vitro*, followed by delivery of the genetically modified cells to the patient. DNA delivery can occur in the patient as naked DNA or within a biological or artificial delivery vehicle. The biological delivery vehicle is usually a virus. A wide variety of artificial delivery vehicles have been developed. They usually consist of lipid vesicles (liposomes) or positively charged polymers that complex with DNA and have a high affinity for cell surfaces that are negatively charged.

Genetic therapy for the treatment of cardiovascular disease (CVD) is in its infant stage despite the large number of potential target genes associated with the development of atherosclerosis. Cardiovascular disease lends itself to genetic therapy because of the focal nature of atherosclerotic lesions and the availability of techniques for direct delivery of the genes to the affected areas. The desire to conduct gene therapy for atherosclerosis is in large part motivated by the large number of transgenic mouse studies in which expression or deletion of a gene has a profound therapeutic effect on the animal. For example, overexpression of the apolipoprotein-A1 gene protects animals from atherosclerosis. A logical extension is to mimic these studies with gene therapy.

Although the gene therapy field is now more than 20 years old, it has not fulfilled its initial promise. From the beginning, it has been impossible to achieve sustained expression of foreign genes at high levels. There is still an incomplete understanding of the fundamental processes by which DNA enters the cells, is transported to the nucleus, integrates into chromosomal DNA, and interacts with transcriptional machinery.

Regardless of the vehicle, DNA must be administered into the circulatory system in order to gain access to a high proportion of cells in a solid tissue. However, most tissues are not in direct contact with blood. They are shielded from blood by a tight layer of endothelial cells that comprise the luminal surface of arteries and veins. Particles as large as viruses or DNA/polymer aggregates cannot cross the small gaps (fenestrae) between endothelial cells. An important exception is the vasculature that perfuses the liver. These vessels have large fenestrae, allowing large particles to gain access to the hepatocytes in the liver. For this reason, it is relatively easy to target the liver and quite difficult to target extrahepatic tissues.

There are three predominant types of viral vectors used in gene therapy; adenoviruses, adeno-associated viruses, and lentiviruses. *Adenoviruses* belong to a family of human DNA tumor viruses that can cause noncancerous respiratory tract infections in humans. Upon infection, the viral DNA remains episomal (outside the host genome), thus making expression transient. Adenoviruses can infect both dividing and nondividing cells. Adenoviral infection causes an inflammatory response, which curtails the infection and can produce severe reactions in some individuals.

Adeno-associated virus is a small nonpathogenic single-stranded DNA virus. On its own, it cannot replicate. It depends on simultaneous expression of genes provided by adenovirus. The virus infects a broad range of dividing and nondividing cells. It can maintain its DNA as an

episome or can, at low frequency, integrate into the host cell's chromosomal DNA. Adeno-associated virus is potentially attractive because its expression tends to be long-lived and it does not elicit an inflammatory reaction the way adenoviruses do.

Lentiviruses are retroviruses, RNA viruses that replicate through a DNA intermediate. HIV is a lentivirus. Lentiviruses have been modified to infect a broad range of cells. They can infect nondividing cells. As is the case with adeno and adeno-associated virus, lentiviruses are produced that are replication-defective for gene therapy applications.

Injection of *naked DNA* into muscle results in transfection of the cells *in vivo*. Intravascular injection of naked DNA leads to uptake by hepatocytes in the liver. Some of the cells stably incorporate the foreign DNA and express its genes. Since animals are continually exposed to foreign DNA coming from the diet and from symbiotic and infectious microorganisms, they have evolved numerous mechanisms to protect their genomes from invasion by foreign DNA. These include degradation by nucleases, inefficient transport to the nucleus, cell death upon DNA uptake, and inactivation of promoters. Naked DNA is still very attractive because it avoids the complications of viral vectors. This justifies a continued effort to overcome the obstacles to efficient and prolonged expression of genes from the naked DNA.

Liposomes are vesicles formed from lipids, usually, phospholipids. Cationic lipids form stable complexes with DNA and can therefore be incorporated into liposomes. These complexes are routinely used by researchers to introduce DNA into cell lines *in vitro*. Their use *in vivo* is attractive because it does not raise the safety issues associated with viral vectors. However, they are far less efficient than viruses so their utility is still limited.

An alternative to direct injection of DNA or a vehicle into a patient is to obtain cells from a patient and incorporate a foreign gene into the cells *in vitro*. Cells that have been selected for stably incorporating the foreign gene can then be given back to the patient. The benefits of this step cannot be overstated; instability of transfected DNA is a major unsolved problem with *in vivo* gene therapy. This approach has been used in atherosclerosis research with cells derived from bone marrow. Since the bone marrow contains precursors of red blood cells and cells of the immune system, this is a practical way to specifically target such cells. After reintroduction to the bone marrow, cells containing a foreign gene enter into the circulation and repopulate tissues. For example, the bone marrow is a source of circulating phagocytic cells (''monocytes'' in the circulation, ''macrophages'' in most tissues, and ''Kupffer cells'' in the liver). Animal experiments have shown dramatic alterations in atherosclerosis susceptibility with the replacement of macrophages in the bone marrow. Partial hepatectomy stimulates a robust regenerative response in the liver. This makes possible the introduction of hepatocytes that have been genetically modified into a partially hepatectomized liver. The new cells respond to the proliferative signals and contribute to the new cell mass of the liver.

2 Atherosclerosis: A Chronic Inflammatory Disease

Atherosclerosis is thought to be the result of a chronic fibro-proliferative

inflammatory response. Animal studies suggest that this inflammatory disease is initiated following the deposition, modification, and retention of lipoproteins within the artery wall. The initial inflammatory response involves the upregulation of expression of *adhesion molecules* and *chemokines* by endothelial cells and smooth muscle cells, leading to the recruitment of monocytes and lymphocytes into the arterial *intima*. The monocytes rapidly convert into tissue macrophages that have the capacity to scavenge modified lipoproteins, secrete proinflammatory *cytokines* and *growth factors*, and further regulate immune functions via presentation of antigens. The *scavenger receptor* mediated uptake of modified lipoproteins transforms the macrophages into lipid-loaded *foam cells*, the accumulation of which is the hallmark of the fatty streak, the initial stage of atherosclerosis (Fig. 1).

The transition of the *fatty streak* into more advanced stages of the disease appears to involve the coalescence of deposited lipids coupled with the death of

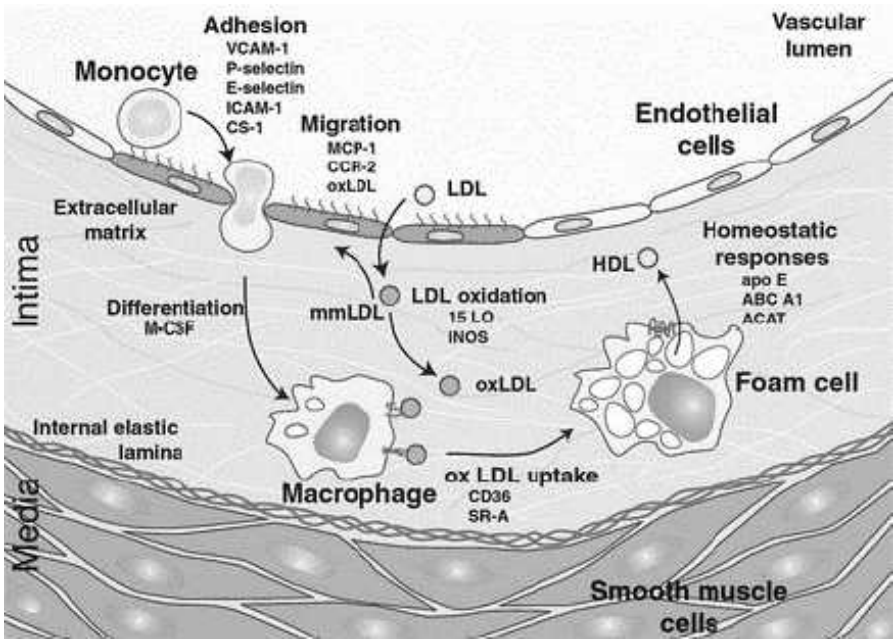

Fig. 1 Initiation of a fatty streak. Lipoproteins such as LDL become trapped within the extracellular matrix of the artery. The trapped lipoproteins are modified by processes such as oxidation or glycosylation (mmLDL, oxLDL) and become proinflammatory leading to the activation of endothelial cells to express adhesion molecules such as VCAM-1 and chemokines such as MCP-1. Monocytes are then recruited into the arterial intima and differentiate into macrophages most likely in response to increased expression of M-CSF. The modified lipoproteins are then taken up by scavenger receptors such as CD36 and the SRA1 expressed by the macrophages and this leads to foam cell formation. The excess cholesterol taken up by the foam cells is esterified by ACAT and stored in lipid droplets. It can be converted back to the more soluble free cholesterol and exported to extracellular HDL acceptors via cholesterol transporters, such as *ABC-A1*. (From Glass, C. K., Witztum, J. L. (2001) Atherosclerosis. The road ahead, *Cell* **104**(4), 503–516, included with permission of the Publisher.)

foam cells to form acellular *necrotic zones*. As in any classical inflammatory response, formation of the necrotic zones is accompanied by a wound-healing response where smooth muscle cells are recruited to encapsulate the necrotic zones by forming a *fibrous cap* around the lipid pools and necrotic debris (Fig. 2). With ongoing hyperlipidemia, however, there is a continuous influx, trapping, and modification of lipoproteins in the developing lesion that recruits additional inflammatory cells and leads to formation of new fatty streaks adjacent to or on top of the initial lesions. The combination of layering of new fatty streaks and erosion of the fibrous cap destabilizes the plaques allowing fissures, ruptures, and intraplaque *hemorrhage* to occur. While the exact mechanisms that cause plaques to rupture are currently unknown, the activation and/or death of macrophages with release of proteolytic enzymes such as *matrix metalloproteinases*, likely play a role. The resulting erosion and rupture exposes procoagulant proteins such as *tissue factor* to the blood and facilitates the formation of mural and *occlusive thrombi* (Fig. 3). The occlusion of the main coronary arteries causes the clinical outcomes of myocardial ischemia, *angina*, and ultimately *myocardial infarction*. Occlusion of cerebral vessels can lead to ischemic stroke while occlusion of peripheral blood vessels

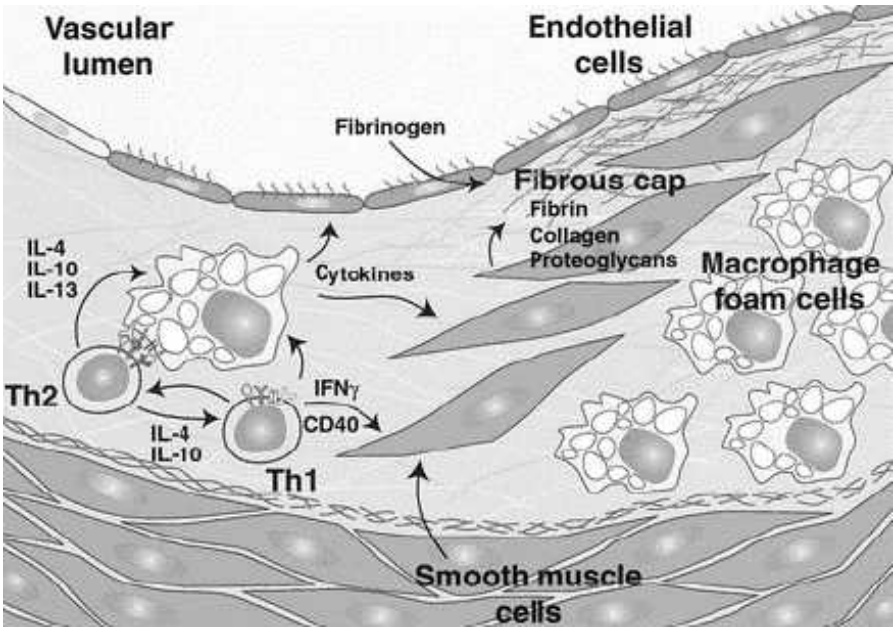

Fig. 2 Atherosclerotic lesion progression. Continued deposition of lipoproteins coupled with foam cell formation and interactions between foam cells, Th1 and Th2 T Helper cells and smooth muscle cells contribute to a chronic inflammatory response. Cytokines secreted by lymphocytes and macrophages exert both pro- and antiatherogenic effects. As part of a wound-healing response smooth muscle cells migrate from the medial portion of the arterial wall, proliferate, and secrete extracellular matrix proteins that form a fibrous cap. (From Glass, C.K., Witztum, J.L. (2001) Atherosclerosis. The road ahead, *Cell* **104**(4), 503–516, included with permission of the Publisher.)

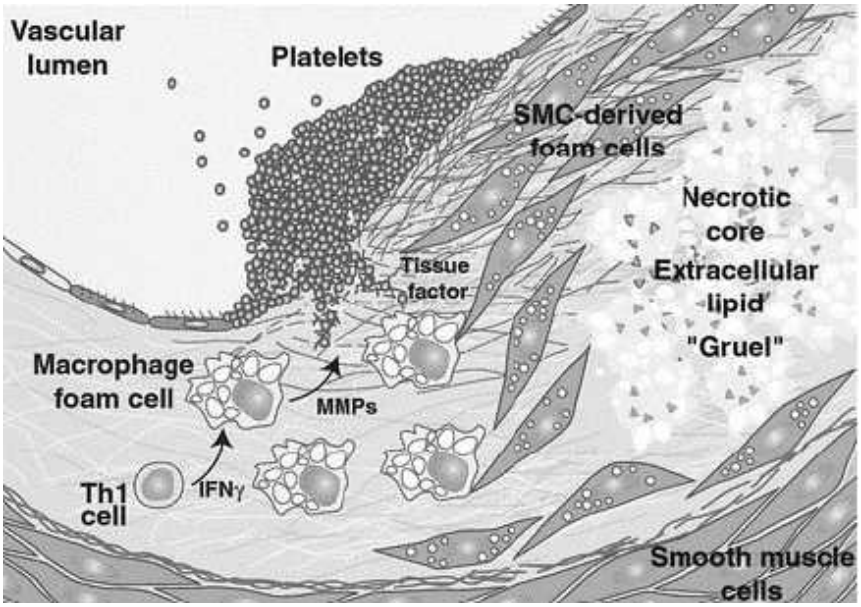

Fig. 3 Plaque rupture and thrombosis. The death of macrophage-derived foam cells and coalescence of trapped lipoproteins leads to the formation of an acellular necrotic zone and accumulation of extracellular cholesterol. Macrophage secretion of matrix metalloproteinases and neovascularization contribute to weakening of the fibrous cap. Plaque rupture exposes blood components to tissue factor, initiating coagulation, the recruitment of platelets, and the formation of a thrombus. (From Glass, CK and Witztum JL, Cell 2001; **104**(4): 503–516, included with permission of the Publisher.)

is associated with critical limb ischemia and gangrene.

3
Gene Therapy Targets for Cardiovascular Disease in the Lipoprotein Pathways

3.1
The Lipoprotein Pathways Provide Many Potential Gene Therapy Targets

A major risk factor for premature atherosclerosis is abnormalities in lipoprotein metabolism. In addition, people with diabetes mellitus frequently have lipoprotein abnormalities that elevate the risk of premature atherosclerosis that is already associated with diabetes.

Lipoprotein metabolism involves the interplay of the intestine, the liver, adipose tissue, and muscle. Endocrine organs also play a role, chiefly pancreatic islets, adrenals, the hypothalamus, and adipose tissue. However, the following discussion will emphasize the role of the liver because it is the most readily accessible target for gene therapy that is based upon the intravenous injection of DNA or DNA within a vector or carrier.

Animals transport large quantities of lipids through the bloodstream on carrier particles called lipoproteins. Lipoproteins consist of a shell of proteins called *apolipoproteins*, amphipathic lipids, primarily phospholipid and unesterified cholesterol, surrounding a core of

Tab. 1 Density, diameter, and composition of plasma lipoproteins.

Class	*Density [g mL^{-1}]*	*Diameter [nm]*	*Chol*	*PL*	*Protein*	*TG*	*CE*
Chylomicrons	0.93	75–1200	2	7	2	86	3
VLDL	0.93–1.006	30–80	7	18	8	55	12
IDL	1.006–1.019	25–35	9	19	19	23	29
LDL	1.019–1.063	18–25	8	22	22	6	42
HDL2	1.063–1.125	9–12	5	33	40	5	17
HDL3	1.125–1.210	5–9	4	35	55	3	13

Notes: Values represent percentage of dry mass. Chol = cholesterol; PL = phospholipids; TG = triacylglycerols; CE = cholesterol esters.

nonpolar lipid. The core composition consists of variable proportions of triacylglycerol and cholesterol ester.

When plasma is subjected to ultracentrifugation, most proteins sediment at the bottom of the centrifuge tube. Because they are associated with lipid and have a low buoyant density, lipoproteins float in the ultracentrifuge. The density at which they float is the basis for their classification (Table 1). In fasting plasma, most of the triacylglycerol is carried by very low-density lipoprotein (VLDL) particles. Cholesterol and cholesterol ester are carried by low-density lipoprotein (LDL) and high-density lipoprotein (HDL) particles, with LDL carrying about two-thirds of all cholesterol in human plasma.

3.2 Specific Genes are Critical for Dietary Lipid Absorption in the Intestine

It is important to remember that ordinarily, the major component of dietary fat is always triacylglycerol, not cholesterol. For example, milk and butter have very little cholesterol but are very high in triacylglycerol. Triacylglycerol (and other glycerolipids, such as phospholipids) is hydrolyzed in the intestinal lumen to yield monoglycerides and free fatty acids. These lipolysis products are then absorbed by the intestinal epithelial cells and resynthesized as triacylglycerols, phospholipids, and cholesterol esters. Thus, the intestine mediates both lipolysis (in the lumen) and reesterification (within the epithelial cells) of dietary lipids. The molecular mechanisms underlying intestinal absorption of fatty acids are still not understood. There is no consensus about whether a specific transporter is involved in fatty acid transport into the enterocytes.

Cholesterol absorption into the enterocyte is also not well understood. A specific inhibitor of cholesterol absorption, Ezetimibe, is in clinical use and is one line of evidence that there is a specific transporter for cholesterol at the membrane of the enterocyte that faces the intestinal lumen (the apical membrane).

The free fatty acids coming from intestinal lipolysis are solubilized into micelles within the intestinal lumen. These micelles consist of bile acids, cholesterol, and phosphatidylcholine. Bile acids are detergent-like molecules produced from cholesterol by the liver. Together with phospholipid and cholesterol, bile acids are secreted from the apical membrane of hepatocytes into the bile canaliculi, which drain into the bile duct and finally into the duodenum. As discussed below,

conversion of cholesterol to bile acids and secretion of biliary cholesterol are the principal routes of cholesterol elimination.

Two membrane cholesterol transporters have been identified in the intestine. One consists of a heterodimer of two proteins, ABCG5, and ABCG8. This pair is located at the apical membrane and transports cholesterol out of the enterocyte into the lumen. In addition, the transporter transports plant sterols and thus protects animals from accumulation of these nonphysiological sterol molecules. Mutations in ABCG5 or ABCG8 cause a rare disease called sitosterolemia, which involves elevated levels of cholesterol and plant sterols in the bloodstream. ABCA1 also transports cholesterol out of enterocytes. In contrast to ABCG5/ABCG8, this transporter appears to transport cholesterol across the basolateral membrane of the enterocyte, to the bloodstream and/or lymphatics. Overexpression of ABCG5/ABCG8 in transgenic mice reduces cholesterol absorption, making this an attractive target for therapeutic intervention.

3.3 The Intestine Exports Lipids on Chylomicron Particles

Since the intestine is primarily an absorptive organ, it must have the means of exporting newly absorbed lipids. The enterocyte reesterifies fatty acids and monoglycerides to form triacylglycerols and phospholipids. Absorbed cholesterol is esterified to form cholesterol esters. Triacylglycerols and cholesterol esters are then packaged into the core of lipoprotein particles unique to the intestine – *chylomicrons*. Rather than being secreted into the bloodstream, chylomicrons are secreted into the lymphatics. By secreting chylomicrons into the lymphatics, they gain entrance into the general circulation via the thoracic duct. This guarantees that extrahepatic tissues, principally adipose tissue and muscle, are the first to be exposed to the newly secreted chylomicrons – if chylomicrons were secreted directly into the bloodstream, they would first be delivered to the liver, via the portal vein.

After entry into the bloodstream, chylomicrons interact with the luminal surface of the capillary beds of adipose tissue and muscle. Here resides the enzyme *lipoprotein lipase*, which hydrolyzes the triacylglycerols all the way to free fatty acids and glycerol. (Cholesterol esters are not substrates for lipoprotein lipase.) The free fatty acids are then absorbed where they are reesterified and stored in triacylglycerol droplets (in adipocytes) or oxidized for energy (in muscle). The chylomicron depleted of its triacylglycerol (a chylomicron remnant) is rapidly cleared from the circulation by the liver. There is significant variation in the abundance and activation state of lipoprotein lipase. This affects the efficiency of clearance of triacylglycerol-rich lipoproteins and is therefore an attractive target for gene therapy.

3.4 The Liver is a Major Producer of Plasma Lipoproteins

Adipose tissue and liver are quite active in the conversion of carbohydrate into fat. Adipose tissue stores the fat in the form of triacylglycerol droplets. However, these droplets are quite dynamic; they are continuously being formed and turned over. The turnover of adipocyte droplets occurs through the action of hormone-sensitive lipase. The free fatty acids that are released from adipocytes can go to the liver where they can be used to make ketone bodies and/or are

reesterified to form triacylglycerol again. Whether derived from adipose tissue or from *de novo* synthesis, the liver does not generally store triacylglycerol. Triacylglycerol accumulation in the liver is generally regarded as a pathological state, termed *fatty liver* or *hepatic steatosis*.

3.5 Lipoprotein Lipase as a Target for Gene Therapy

In a healthy liver, triacylglycerol is packaged for secretion within the secretory pathway. This involves transfer of triacylglycerol to the endoplasmic reticulum lumen and interaction with apoB100 (Fig. 4). Within the secretory pathway, there are several steps in which triacylglycerol is incorporated into a growing VLDL particle. VLDL is then secreted into the bloodstream. Like chylomicrons, VLDL interacts with *lipoprotein lipase* while in the circulation. However, unlike chylomicrons, the depletion of triacylglycerol from VLDL yields a VLDL remnant, also termed *intermediate density lipoprotein* (IDL), which goes on to produce a stable lipoprotein,

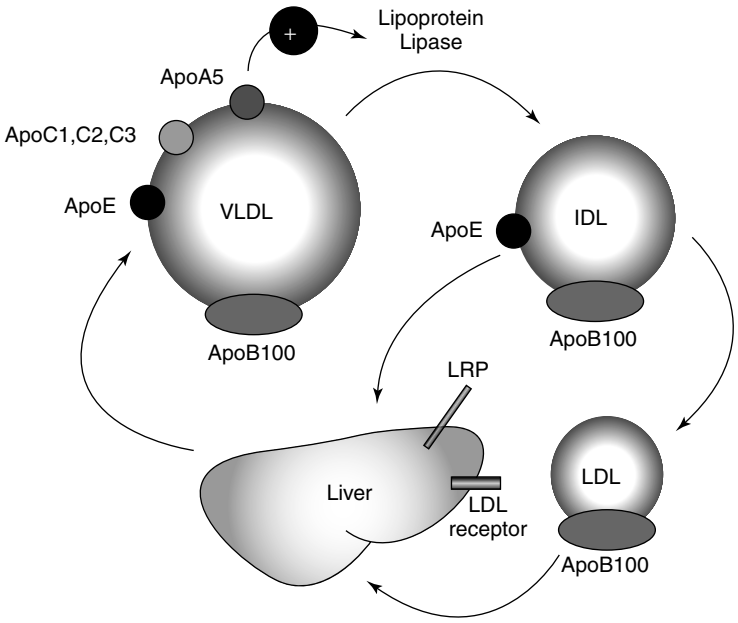

Fig. 4 Metabolic interrelationships of liver-derived plasma lipoproteins. The liver secretes VLDL, a particle enriched in triacylglycerol. It carries various apolipoproteins. ApoB100 is the only nonexchangeable protein on VLDL particles. ApoC2 and possibly, apoA5, are activators of lipoprotein lipase. This enzyme resides on the luminal surface of the capillary endothelium of adipose tissue and muscle and hydrolyzes the fatty acids from VLDL triacylglycerols. The resulting particle, IDL, can be cleared from the circulation by the liver or can become LDL. Clearance of IDL is mediated by apoE. Clearance of LDL is mediated by apoB100. The LDL receptor plays a critical role in the clearance of IDL and LDL; both apoE and apoB100 can bind to the LDL receptor. The LRP acts as a backup for IDL clearance; in the absence of the LDL receptor, it can clear IDL by binding to apoE.

LDL. Owing to the loss of most of the triacylglycerol, the predominant neutral lipids of LDL are cholesterol and cholesterol ester.

The catabolism of VLDL is dependent upon efficient hydrolysis of its triacylglycerol core by lipoprotein lipase. Lipoprotein lipase deficiency results in dramatic hypertriglyceridemia, liver enlargement (hepatomegaly), and inflammation of the pancreas (pancreatitis). However, elevated plasma VLDL can result from many other as-yet unidentified causes. It is very common in the human population and is associated with obesity, diabetes, and in some individuals, high-carbohydrate diets. Although these individuals have normal levels of lipoprotein lipase, increasing the level of this enzyme might still be a useful therapeutic strategy to lower plasma triacylglycerols. Since it is presently not feasible to target genes to the normal sites of expression of lipoprotein lipase (muscle and adipose tissue), expression in a nonphysiological site, the liver, has been tested in mice and in a naturally occurring feline model of lipoprotein lipase deficiency.

In addition to the expected role of lipoprotein lipase in catalyzing the hydrolysis of lipoprotein triacylglycerol, there is also a nonenzymatic property of potential therapeutic value. Lipoprotein lipase binds to lipoproteins and also binds to lipoprotein receptors in the LDL receptor family, most notably, the LDL receptor-related protein (LRP). In addition, lipoprotein lipase can bind to cell surface proteins that are enriched in acidic carbohydrate residues, the proteoglycans. The best evidence that these nonenzymatic functions are therapeutically relevant is the demonstration that a mutant form of lipoprotein lipase lacking enzymatic activity is still able to reduce plasma triacylglycerol by about 20 to 30%.

Lipoprotein lipase-mediated hydrolysis of triacylglycerol causes fatty acids to be taken up at the site of hydrolysis. In the liver, this leads to reesterification of the fatty acids and can result in an increase in cellular triacylglycerols. Through mechanisms not clearly understood, excessive triacylglycerol accumulation dampens the cell's responsiveness to insulin. In the liver, insulin normally suppresses glucose production. Thus, one potential side effect of expression of lipoprotein lipase in the liver is to reduce the ability of insulin to suppress glucose production, a potential problem for people who are already insulin-resistant or diabetic.

3.6 The LDL and VLDL Receptors are Attractive Targets for Gene Therapy

LDL is cleared from the circulation in large part through its interaction with the *LDL receptor*. Mutations affecting the expression or function of the LDL receptor are responsible for a common inherited disorder, *familial hypercholesterolemia*. Increased expression of the LDL receptor reduces LDL levels; thus, the LDL receptor has been used in gene therapy for hypercholesterolemia.

The VLDL receptor is a member of the LDL receptor family. It is expressed in a wide range of tissues, but not in the liver. However, adeno-associated virus was used to express this receptor in the livers of mice lacking the LDL receptor. These mice experienced a 40% reduction of cholesterol, due to enhanced clearance of both VLDL and LDL. Since patients who do not express the LDL receptor are immunologically naïve to this antigen, gene therapy with the VLDL receptor might be an effective treatment that would avoid the danger of immune rejection.

3.7

Increased Cholesterol and Phospholipid Efflux via ABCA1 Can Prevent Atherosclerosis

Epidemiological studies show an inverse relationship between HDL levels and risk of premature atherosclerosis. Unlike VLDL and chylomicrons, HDL is formed from its protein and lipid components in the bloodstream and interstitial fluids rather than within the secretory pathway of cells. The major apolipoproteins of HDL are apoA1 and apoA2. These proteins are secreted from hepatocytes and intestinal epithelial cells independently and also as minor components of VLDL and chylomicrons. ApoA1 and apoA2 bind to phospholipids. Phospholipids are available from the surface of VLDL after lipolysis. In addition, cells are able to efflux phospholipids and cholesterol through the action of ABCA1 (Fig. 5). Its crucial role in this process was established by the discovery that two types of severe inherited HDL deficiency syndromes are caused by mutations in ABCA1, Tangier Disease, and familial hypoalphalipoproteinemia (FHA).

Tangier Disease is a rare recessive disorder in which patients have almost no HDL. Cholesterol ester accumulates in macrophages and macrophage-rich tissues like spleen and liver. FHA is a very common dominant disorder in which people have low HDL (typically <30 mg dL^{-1}) and suffer from premature heart disease even without an elevation in LDL. Approximately 40% of patients with premature coronary heart disease have low HDL, making it the most common lipid disorder of heart disease patients.

Tangier Disease and FHA are caused by mutations in ABCA1. Tangier Disease patients are homozygous (or inherit two different mutant alleles). FHA patients are heterozygous for mutations at the ABCA1 locus. ABCA1 mutations lower HDL because they prevent phospholipid and/or cholesterol from effluxing and becoming associated with apoA1 and apoA2. In the absence of sufficient lipid, apoA1 is rapidly cleared by the kidneys.

Why do mutations in ABCA1 lead to premature heart disease? ABCA1 fulfills a rate-limiting step in the pathway by which cells get rid of cholesterol, and thus might be a critical protector against cholesterol overload. With the exception of hepatocytes, cells are unable to catabolize large quantities of cholesterol and must therefore protect themselves from cholesterol overload by expelling cholesterol to an appropriate extracellular carrier. It is interesting that ABCA1 is especially abundant in macrophages; macrophages can become engorged with cholesterol esters and form foam cells in the arterial wall. A mutation in ABCA1 might therefore predispose an individual to atherosclerosis by impeding cholesterol efflux (Fig. 1).

Proof-of-principle studies in mice nominate ABCA1 for the gene therapist's arsenal. Moderate overexpression of ABCA1 decreases atherosclerosis in mice, despite having a minimal effect on HDL levels. The most plausible explanation is that macrophage ABCA1 function is more important than HDL levels in protecting an animal from atherosclerosis. Indeed, if animals are transplanted with macrophages derived from mice lacking ABCA1, they show increased atherosclerosis. These animal studies suggest that increased expression of ABCA1 in macrophages might be a sensible gene therapy strategy for protection against or treatment of atherosclerosis.

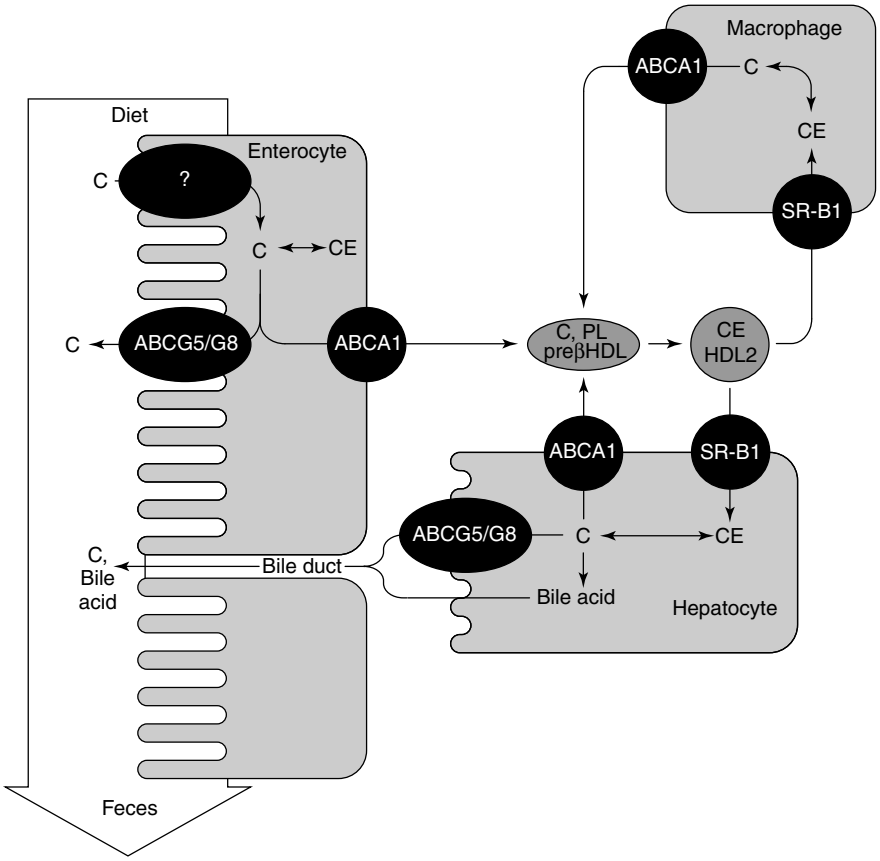

Fig. 5 ABC transporters involved in cholesterol transport. ABCG5 and ABCG8 function together as a heterodimer and mediate the transport of cholesterol from hepatocytes across the canalicular (apical) membrane into the bile. The ABCG5/G8 complex is also involved in cholesterol and plant sterol efflux from the enterocytes of the intestine to the intestinal lumen. This reduces the net absorption of cholesterol and prevents absorption of plant sterols. ABCA1 transports cholesterol and phospholipids on the sinusoidal (basolateral) surface of hepatocytes and enterocytes. In addition, ABCA1 is abundant in macrophages where it mediates cholesterol and phospholipid efflux. ApoA1 interacts with ABCA1 and mediates the formation of precursors to HDL (preβHDL). The esterification of the cholesterol in the preβHDL by the blood-borne enzyme, lecithin cholesterol acyl transferase (LCAT), produces mature HDL. Mature HDL can bind to the SR-B1 receptor and deliver cholesterol esters to hepatocytes. Much of the cholesterol ester is thus delivered and hydrolyzed by a cellular cholesterol esterase and secreted into bile as unesterified cholesterol.

3.8 Some Apolipoproteins Can Prevent Atherosclerosis

ApoA1 is a major protein constituent of HDL. It is an activator of an enzyme in the bloodstream, LCAT. This enzyme transfers a fatty acid from the *sn*-2 position of phosphatidylcholine to cholesterol to form a cholesterol ester. It enables HDL to ''accept'' cholesterol from cells or other lipoproteins and then to fill its

core with the cholesterol by esterifying it. ApoA1 also interacts with ABCA1 to mediate cholesterol and phospholipid efflux from cells.

Overexpression of apoA1 in transgenic mice or injection of large quantities of the apoA1 protein produces dramatic effects on atherosclerosis – both prevention and regression of atherosclerotic lesions. ApoA1 overexpression is a very attractive prospect for gene therapy. The biggest difficulty is that apoA1 levels in human plasma are already quite high, $\sim$1 mg mL^{-1}. Thus, with present technology, it would be quite difficult to achieve a significant increase in this steady state level.

ApoA5 is a newly discovered apolipoprotein that is associated with VLDL. Its deletion in mice results in elevated triacylglycerols and its overexpression in transgenic mice drives down triacylglycerol levels. It is likely that it plays a role in the ability of lipoprotein lipase to hydrolyze VLDL triacylglycerol. ApoA5 might be an attractive candidate for gene therapy of hypertriglyceridemia.

ApoE is a ligand for the LDL receptor and virtually all other members of the LDL receptor family. It is associated with VLDL and chylomicrons and to a varying extent, with HDL. Chylomicrons depend on apoE for their clearance from the circulation. In addition, although VLDL does have another competent LDL receptor ligand, apoB100, VLDL remnants are inefficiently cleared in the absence of apoE. There are three common allelic variants of apoE – apoE2, apoE3, and apoE4. ApoE2 has a greatly reduced affinity for its receptors and is therefore associated with impaired clearance of VLDL and chylomicron remnants. From these properties, one might predict that increasing apoE levels might be therapeutically desirable by promoting efficient removal from the circulation of remnant lipoproteins. However, studies in transgenic mice and rabbits revealed two unexpected consequences of apoE overexpression. First, increased apoE synthesis in the liver leads to increased VLDL production. Second, increased apoE in the VLDL particle slows the hydrolysis of triacylglycerol by lipoprotein lipase.

3.9 The Liver SR-B1 Receptor Protects against Atherosclerosis

The scavenger receptor-B1 (SR-B1) is highly expressed in tissues that actively convert cholesterol into steroid hormones; for example, adrenals, ovaries, and testis. It is also highly expressed in hepatocytes. SR-B1 binds to HDL and mediates the selective uptake of cholesterol ester from the HDL particle into the cell. Unlike the uptake of LDL particles, the particle itself is spared and can then recycle back to pick up another cargo of cholesterol. The overexpression of SR-B1 in transgenic mice causes a drastic drop in HDL levels and protects the animals from atherosclerosis. Conversely, disruption of the gene raises HDL and increases the susceptibility of animals to atherosclerosis. Interestingly, increased SR-B1 expression increases the secretion of cholesterol into the bile, indicating that uptake of cholesterol from HDL effectively targets the HDL toward biliary secretion.

The foregoing might seem to contradict the known inverse relationship between HDL levels and atherosclerosis. However, increased HDL can be due to increased HDL production or decreased HDL turnover. Increased HDL production is thought to be beneficial because it promotes cholesterol flow back to the liver. However, increased HDL, if it is due to an

impairment in its ability to deliver cholesterol to the liver, is not beneficial. The transgenic experiments in mice suggest that increased SR-B1 expression in the liver might be a viable approach to gene therapy for atherosclerosis.

4 Vascular and Inflammatory Targets for Gene Therapy

Small clinical trials of gene therapy for cardiovascular disease have been limited to induction of *angiogenesis* in the heart and legs for the treatment of *angina* and critical limb *ischemia* or to blocking of the proliferative response following injury induced by *angioplasty* and vascular grafting as a means of preventing *restenosis*. These trials have involved use of adenoviruses and DNA-containing liposomes for localized overexpression of angiogenic growth factors such as vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF), hepatocyte growth factor (HGF) and antisense oligonucleotides or decoy oligonucleotides for inhibiting expression of cell cycle genes such as *c-Myc* or for preventing binding of transcription factors such as E2F to cis-acting response elements respectively. The localized overexpression of VEGF and other growth factors in the heart and limbs have had mixed results with some recorded successes in formation of collateral vessels, increased blood flow, and reduced pain. Large-scale clinical trials in the United States have been slowed because of the problems with virus-related inflammation and with VEGF-induced edema.

As discussed in the first section of this chapter, genes involved in lipid and lipoprotein metabolism are potential targets for reducing hyperlipidemia and the consequent deposition and retention of lipids and lipoproteins in the artery wall. However, there are still a considerable number of individuals who develop cardiovascular disease who do not have appreciably elevated lipids or are resistant to current therapies. Thus, other targets need to be considered. Genes involved in regulating leukocyte function and the inflammatory response within the artery wall are potential candidates.

4.1 Adhesion Molecules and Leukocyte Counter Receptors

The *adhesion molecules*, vascular cell adhesion molecule (VCAM-1) and intercellular adhesion molecule (ICAM-1), are members of the immunoglobulin superfamily of proteins. Together with their leukocyte counter receptors, the integrins VLA4 and MAC-1/CD11b:CD18, are potential targets for gene therapy. VCAM-1 and ICAM-1 are expressed by endothelial cells and support the tight binding of monocytes and lymphocytes to the endothelial cell plasma membrane. The selectins (E-, P-, and L-selectins) are also adhesion molecules that play a role in the initial tethering and rolling of leukocytes along the surface of the blood vessel. They are lectin-like molecules that recognize carbohydrate containing counterreceptors.

Knockouts of ICAM-1, E-, and P-selectins in mice all partially inhibit development of atherosclerosis. Thus, localized inhibition of expression of these genes might prevent initiation of lesions and limit progression of established lesions due to layering and the continuous influx of leukocytes. Adenovirus-mediated gene transfer to endothelial cells has been successful in both *in vitro* and *in vivo* studies and suggests that this approach could

be used for inhibiting expression of the adhesion molecules.

The transient nature of adenoviral-mediated gene transfer is a cause for concern. Given that the atherosclerotic lesions develop over several decades, effective adenoviral therapy would require repeated injections. The use of retroviruses or adeno-associated viruses to incorporate the gene into the cellular genome might be a better alternative. However, this approach is also limited by the small percentage of endothelial cells that proliferate under normal circumstances. Blocking expression of the leukocyte integrins is even more problematic. Currently, this would require transfection of bone marrow stem cells and would likely compromise the capacity to mount an inflammatory response at other sites. Overexpression of secreted forms of the adhesion molecules may be an effective alternate approach.

4.2 Cytokines

Cytokines are cell regulatory proteins that are key factors in the initiation and control of inflammation. They are classified as members of several different families of proteins that include: the tumor necrosis factor (TNF) family, interleukins, interferons, colony-stimulating factors, growth factors, and chemokines. There are significant overlaps in the functions of many of the cytokines. This overlap is in part due to the convergence of signal transduction pathways from the different cytokine specific receptors leading to activation of the same transcription factors. However, in other cases cytokines can have opposite effects and are frequently designated as being either proinflammatory or anti-inflammatory. Serum cytokine levels are elevated in people with established cardiovascular disease. Virtually, every major pro- and anti-inflammatory cytokine is expressed by cells within atherosclerotic lesions and all vascular cell types are capable of responding to these proteins. Thus, there is significant potential for the inhibition and treatment of CVD by manipulating the production of or response to cytokines using gene transfer approaches.

4.3 Chemokines and Chemokine Receptors

Monocyte chemotactic protein (MCP-1) and IL-8 are two potent leukocyte chemoattractants (*chemokines*) that play a role in recruiting leukocytes into the sites of inflammation. MCP-1 is expressed by all of the cell types within atherosclerotic lesions. Recent data from studies on atherosclerosis-prone mice with targeted deletion of MCP-1 or the chemokine receptors CCR-2 or CXCR-2, and studies of bone marrow transplantation of cells overexpressing MCP-1 or devoid of IL-8, strongly suggest that these molecules play a critical role in the initiation of fatty streaks.

Recent gene therapy studies with an N-terminal deletion mutant of the human MCP-1 gene transfected into the skeletal muscle of the atherosclerosis-prone apoE knockout mice have demonstrated the potential for inhibiting atherosclerosis by blocking MCP-1 activity. However, as with the adhesion molecules, there are caveats with regard to targeting the MCP-1, IL-8, and/or CCR-2 and CXCR-2 genes for CVD gene therapy. Because MCP-1 is expressed by all of the cells within the lesions and IL-8 primarily by macrophages, it is unclear whether adenoviral or retroviral approaches would be successful in inhibiting MCP-1 or IL-8 expression by macrophages.

Primary macrophages are extremely difficult to transfect, therefore, blocking their capacity for expressing MCP-1, IL-8, or the receptors likely would require repeatedly knocking out the genes in bone marrow cells. This again raises the question, to what extent would this compromise the inflammatory response at other sites. Thus, localized overexpression of mutated forms of these proteins such as the N-terminal deletion mutant sited above is the most logical approach to targeting chemokines for prevention and treatment of cardiovascular disease.

4.4 Interleukins, the TNF-α family, and Interferon-γ

Currently, *in vitro* and limited *in vivo* data suggest that IL-1, IL-2, TNF-α, IL-3, IL-6, IL-12, IL-15, and IL-18 appear to have proatherogenic properties, while the IL-1 receptor antagonist (IL-1ra), IL-9, IL-10, IL-11 and possibly IL-4, and IL-13 are likely to be antiatherogenic. Thus, localized inhibition of proatherogenic cytokines and overexpression of antiatherogenic cytokines with gene therapy has significant potential for prevention and treatment of cardiovascular disease.

TNF-α and IL-1-β are the proinflammatory cytokines that have received the most attention. *In vitro* studies have clearly demonstrated that these two cytokines potently stimulate the expression of adhesion molecules and chemokines and suggest that they play an important role in the atherogenic process. Surprisingly, targeted deletion of TNF-α or the p55 TNF-α receptor is not protective of atherosclerosis in mouse models. Furthermore, the chronic administration of a TNF-α binding protein reduces fatty streak formation only in female apoE knockout mice. The effects of deletion of IL-1 on atherosclerosis have not been reported. However, in knockouts of the IL-1ra, there was a trend toward increased foam-cell lesion area compared with the wild-type littermate controls. Successful gene therapy studies in animal models of cerebral, pancreatic, and articular inflammation with IL-1ra further support the potential for this approach to cardiovascular disease.

CD40 and CD40 ligand are members of the TNF receptor and protein families respectively. They are expressed by monocytes, macrophages, dendritic cells, lymphocytes, endothelial cells, and smooth muscle cells and play a role in many inflammatory processes including the expression of adhesion molecules, cytokines, chemokines, and matrix metalloproteinases. Recent data suggests that CD40/CD40 ligand play fundamental roles in the atherogenic process as CD40 ligand–apoE double knockout mice have significantly reduced atherosclerosis and lesions that contain reduced numbers of inflammatory cells, are connective tissue rich, and are likely resistant to plaque rupture. Thus, CD40 or CD40 ligand are both additional potential targets for localized CVD gene therapy.

Interferon gamma (IFN-γ) is an immuno-stimulatory cytokine that increases antigen presentation by macrophages and the activation of T lymphocytes. As macrophages and T lymphocytes are key cellular components of the atherosclerotic lesions at all stages of lesion development, gene therapy that targets IFN-γ expression could have a significant impact on the disease process. This is supported by several studies in mice that demonstrate a critical role for this cytokine. For example, atherosclerotic lesions are significantly reduced in IFN-γ-deficient mice crossed with either LDL-receptor

knockout or apoE knockout mice and are increased with chronic administration of recombinant IFN-γ. Interleukin-18 (IL-18) in part promotes inflammatory responses through the release of IFN-γ. Administration of recombinant IL-18 to apoE knockout mice, like the administration of IFN-γ, significantly increases lesion size. Not surprisingly, in IFN-γ/apoE double knockout mice, there are no effects of IL-18 on lesion development.

IL-2 is another interleukin with probable proatherogenic properties. It also functions to alter T-lymphocytes by affecting a shift to a Th1 T helper cell phenotype. It is expressed within atherosclerotic lesions and serum levels are increased in people with ischemic heart disease and unstable angina pectoris. However, to date, IL-2 has not been shown to play a direct role in the development of lesions in animal models. In contrast to IL-2, IL-4 and IL-10 in part function to cause a shift toward an antiatherogenic Th2, T helper cell phenotype. There is reduced atherosclerosis in LDL-receptor knockout mice transplanted with bone marrow from IL-4 deficient mice but no increase in atherosclerosis in cholesterol-fed, IL-4 deficient mice. On the other hand, fatty streak formation in IL-4-deficient mice immunized with HSP65 or Mycobacterium tuberculosis is significantly reduced when compared with lesions in wild-type C57BL/6 mice.

In addition to causing a Th2 shift, IL-10 inhibits differentiation of monocytes to macrophages, macrophage presentation of antigens, generation of reactive oxygen and nitrogen species, and endothelial cell expression of ICAM-1. There is accelerated formation of atherosclerotic lesions in IL-10 knockout mice and reduced formation of lesions in IL-10 transgenic mice. Thus, localized overexpression of IL-4 and IL-10 could provide some protection against cardiovascular disease. There is also recent evidence that IL-6 may play a role in the development of atherosclerosis. Treatment of fat-fed C57BL/6 or apoE knockout mice with recombinant IL-6 significantly increases fatty streak formation.

4.5 Growth Factors and Receptors

Growth factors are potent regulators of cellular functions including proliferation, migration, differentiation, and survival/apoptosis. Many growth factors and growth factor receptors are expressed or deposited in atherosclerotic lesions. These include all forms of platelet-derived growth factor (PDGF), basic fibroblast growth factor (bFGF), vascular endothelial growth factor (VEGF), insulin-like growth factors (IGF-1 and IGF-2), thrombin, endothelin-1, angiotensin-II, heparin binding-epidermal growth factor (Hb-EGF), several forms of transforming growth factor-beta (TGF-β), and the hematopoietic growth factors: macrophage colony-stimulating factor (M-CSF), granulocyte colony–stimulating factor (G-CSF), and granulocyte-macrophage colony-stimulating factor (GM-CSF).

The original ''Response to Injury'' hypothesis of Glomset and Ross posited that denuding injury to the endothelium led to the activation and attachment of platelets with release of PDGF. This was thought to lead to increased smooth muscle cell migration and proliferation and development of atherosclerotic lesions. Over the past three decades, the paradigm has shifted to account for the crucial role of inflammatory cells and the potential protective role of smooth muscle migration and proliferation in the formation of the fibrous cap (Figs. 1–3). Thus, for gene therapy approaches to CVD, localized overexpression

of growth factor genes could help stabilize lesions at risk of rupture and thrombosis. As proof of principle, transplant of fetal liver cells from mice deficient in PDGF-BB or chronic treatment with a PDGF-receptor antagonist or anti-PDGF receptor antibodies in apoE knockout mice leads to the formation of lesions that contain mostly macrophages, appear less mature, and have a reduced frequency of fibrous cap formation as compared with control mice. In contrast to primary atherosclerotic lesions, smooth muscle migration and proliferation contributes to *restenosis* following angioplasty and other interventions. Gene therapy approaches to inhibiting growth factor expression postinjury have been in development for several years.

Stimulating or inhibiting the expression of individual growth factors alone may not be sufficient to control vascular smooth muscle cell migration and proliferation. This is because both smooth muscle cell migration and proliferation are exceedingly complex processes and involve dissociation from the extracellular matrix through the activation and secretion of proteases, engagement of multiple growth factor receptors with activation of a variety of receptor associated and cytoplasmic kinases, activation of transcription factors, and production and activation of proteins involved in cell cycle traverse and DNA synthesis such as cyclins and cyclin-dependent kinases. Thus, there are potentially many targets other than growth factors or their specific receptors for gene therapy. This has been demonstrated by the ongoing clinical trials previously cited where antisense oligonucleotides or decoy oligonucleotides for inhibiting expression of cell cycle genes such as *c-Myc* or for preventing binding of transcription factors such as E2F are being tested as the means of preventing restenosis following angioplasty.

The hematopoietic growth factors M-CSF and GM-CSF play a role in the differentiation of monocytes and possibly in regulating macrophage proliferation and death within atherosclerotic lesions. Thus, these factors may also be good targets for gene therapy for both early and unstable lesions. This has been supported by data showing that M-CSF deficient mice crossed with apoE knockout mice have significantly reduced atherosclerosis. Furthermore, chronic administration of an antibody that blocks the M-CSF receptor (c-fms) also reduces early lesions in apoE knockout mice.

Angiogenic growth factors such as the VEGFs, HGF, and the angiopoietins have already been mentioned with regard to ongoing clinical trials for the induction of collateral circulation in people with occluded coronary and peripheral arteries. However, small *neovessels* also form in advanced atherosclerotic lesions and are additional conduits for recruitment of leukocytes into the established lesions. Blocking *neovascularization* could help reduce inflammation and stabilize the lesions. Thus, localized inhibition of expression of these factors or their respective receptors (FLT and FLK for VEGFs and Tie receptors for angiopoietins) are potential additional CVD targets.

5
Pro- and Antioxidant Enzymes

There is now ample evidence that polyunsaturated fatty acids, phospholipids, and cholesteryl-esters within lipoproteins that become trapped within the extracellular matrix of the artery wall can become oxidized. *In vitro* studies have demonstrated that macrophage scavenger receptors

(MSR) recognize oxidized lipoproteins and that foam cell formation is due in part to the accumulation of oxidized lipoproteins. The uptake of oxidized lipids can lead to intense oxidative stress within the foam cells and likely contributes to cell death.

It is currently unclear exactly how lipoproteins are oxidized within the artery wall. Several lines of evidence indicate that proinflammatory enzymes such as myeloperoxidase and the lipoxygenases can oxidize lipoproteins. Macrophages also express the bacteriocidal enzymes NADPH oxidase and the inducible form of nitric oxide synthase that generate the superoxide anion and nitric oxide respectively. These reactive oxygen and nitrogen species can also contribute to lipoprotein modification and oxidative stress within foam cells. Thus, it is possible that gene therapy could be used to inhibit expression of these enzymes within atherosclerotic lesions and thus reduce formation of the necrotic zones and help stabilize lesions that are susceptible to plaque rupture and thrombosis. This is supported by studies showing that mice deficient in 5-lipoxygenase or 12/15 lipoxygenase are protected from atherosclerosis and that mice transgenic for 12/15 lipoxygenase have accelerated formation of lesions.

In contrast to the lipoxygenases, knockout of myeloperoxidase and the NADPH oxidase subunits do not protect mice from atherosclerosis. As with other essential proinflammatory factors, a deficiency of these enzymes can have a significant effect on the capacity to mount an inflammatory response as is seen in people with a deficiency of NADPH oxidase and the resulting chronic granulomatous disease. Thus, future gene therapy to inhibit the expression or activity of these enzymes will require viral targeting to leukocytes only within the artery wall.

All cell types have protective mechanisms against the buildup of pro-oxidants that could disrupt cellular functions by oxidizing lipids, proteins, and DNA. These protective mechanisms include formation of the primary endogenous antioxidant glutathione by the enzyme complex glutamate cysteine ligase. Glutathione acts by enzymatically and chemically converting electrophilic centers to thioether bonds and as a substrate in the glutathione peroxidase mediated destruction of hydroperoxides. Complete glutathione redox systems are located in both the mitochondria and cytoplasm. Reduction of oxidized glutathione by glutathione reductase utilizes reducing equivalents supplied by NADPH and consumes NADPH at a higher rate than most other NADPH-dependent enzymes. Under conditions of oxidative stress with active glutathione redox cycling (as would occur in foam cells containing increased lipid peroxides), the cell's supply of glutathione and NADPH can be depleted, thus limiting many important redox sensitive and biosynthetic reactions and can lead to cell injury and death. Cells also contain superoxide dismutases that convert the superoxide anion to hydrogen peroxide and the enzyme catalase that converts hydrogen peroxide to water. Thus, targeted overexpression of the enzymes involved in glutathione metabolism – the superoxide dismutases and/or catalase could help reduce oxidative stress and foam cell death.

6 Scavenger Receptors

There are now known to be at least three families of broad specificity *scavenger receptors* that are expressed primarily by

macrophages within human atherosclerotic lesions. These include the type A family (subtypes I–III and the *ma*crophage *r*eceptor with *co*llagenous structure or MARCO), type B receptors that include CD36, SR-B1/CLA-1 and the splice variant SR-B2, and an additional group of receptors such as the mucin-like receptor macrosalin/CD68 and LOX-1. All of these receptors bind oxidized LDL, but CD36 now appears to be the major receptor on macrophages responsible for accumulation of oxidized LDL.

Recent studies of hyperlipidemic mice with targeted deletions of SRA I/II or CD36 have clearly established that both types of receptors play a fundamental role in foam cell formation and lesion development *in vivo*. Macrophages within human lesions also express a specific receptor that recognizes advanced glycosylation end-product (AGE) proteins, the LDL receptor, VLDL receptor, and the LDL-receptor related protein/α_2-macroglobulin receptor (LRP). Because all of these receptors are expressed primarily by macrophages, this again brings up the problem that primary macrophages are extremely difficult to transfect and blocking their capacity for expressing scavenger receptors would likely require repeatedly knocking out the genes in bone marrow cells. Like adhesion molecules, an alternate approach that should be effective is the overexpression of soluble decoy scavenger receptors that would bind and clear modified lipoproteins and reduce lipoprotein trapping in the artery wall and the subsequent formation of foam cells. This is supported by a recent study showing that there is reduced atherosclerosis in LDL-receptor deficient mice treated with an adenoviral construct containing the human MSR AI extracellular domains.

7 Transcription Factors

Decoy oligonucleotides have been used to block binding of activated transcription factors to their consensus DNA response elements in the promoters of many genes. This may be a viable approach to reducing expression of many cytokines and other proinflammatory factors *in vivo* because activation of transcription factors such NF-κB, AP-1, and the STAT proteins are end points common to signal transduction pathways activated by various proinflammatory stimuli. Blocking the activation or expression of NF-κB could be a particularly effective therapy as there is activated NF-κB in all of the cell types within atherosclerotic lesions. In addition to blocking activation of NF-κB with decoy oligonucleotides, stimulating the activity of the natural inhibitors of NF-κB, the I-κB proteins, or inhibiting the expression or activity of the I-κB kinases that phosphorylate the I-κB proteins leading to the proteosomal degradation of the NF-κB inhibitors, may also be viable approaches. Targeting the expression of the NF-κB subunits p65 and p50 is another possible approach. Other transcription factors such as Egr-1, Nrf-1, and Nrf-2 may also be potential targets for cardiovascular disease. Egr-1 is an essential factor for regulating the expression of tissue factor, a key procoagulant protein expressed by cells in atherosclerotic lesions. Nrf-1 and Nrf-2 are important factors for regulating the expression of pro- and antioxidant enzymes and bind to consensus antioxidant response elements of these genes.

8
Noninflammatory Gene Targets

There are a large number of proteins that are not directly part of the inflammatory response that are potential targets for CVD gene therapy. These include proteins that regulate cell death, cellular proteases that may play a role in breaking down the arterial extracellular matrix, proteins that play a role in regulating blood pressure and vascular tone, pro- and anticoagulant proteins, and osteogenic proteins that may contribute to vascular calcification.

8.1
Cell Death

As noted, the death of macrophages likely plays a fundamental role in the formation of the necrotic zones of advanced lesions. There is ample evidence showing the presence of macrophages with fragmented DNA (a marker of cell death) located within or adjacent to these necrotic zones. The death of smooth muscle cells also plays a role in the thinning of the fibrous cap, and like the macrophages, smooth muscle cells with fragmented DNA have been documented within atherosclerotic lesions from both humans and experimental animals. Thus, strategies designed to reduce cell death within atherosclerotic lesions could help stabilize the plaques and prevent plaque rupture and formation of occlusive thrombi.

Although it is currently unclear what induces the death of either cell type *in vivo*, there is *in vitro* evidence that apoptosis (programmed cell death or cellular suicide) can be induced in both macrophages and smooth muscle cells by oxidized lipids and other proinflammatory factors. Thus, proteins known to play a role in apoptotic death are potential targets for gene therapy. These include death-promoting proteins such as Fas (a death receptor that is a member of the TNF-α receptor family) and the Fas ligand, the cysteine proteases (caspases 3, 8, 9), and other death pathway effector proteins such as Fas-associated death domain (FADD) (Fas-associated protein with death domain), TNF receptor associated death domain (TRADD) (TNF receptor associated death domain protein), TRAF (TNF receptor associated factor), and receptor interacting protein (RID). There are also a number of antiapoptotic proteins such as c-FLIP (Fas-associated death domain (FADD) protein (FADD)-like interleukin-1 beta-converting enzyme [FLICE (caspase-8)]-inhibitory protein), BCL-2 and BCL-X that could provide protection against cell death if locally overexpressed.

8.2
Proteases

Secretion of proteolytic enzymes such as the matrix metalloproteinases (MMPs) by cells within the blood vessel plays an essential role in enabling the cells to migrate and proliferate. However, excess secretion of these enzymes by activated leukocytes or release of lysosomal enzymes such as cathepsins following the death of cells likely contributes to the breakdown of the extracellular matrix and to the fissure and rupture of the plaques. This is supported by data showing the presence of activated MMPs in unstable human atherosclerotic plaques. Thus, strategies designed to inhibit the expression of these proteolytic enzymes or the activation of the zymogen forms by membrane-associated enzymes such as the ADAM family of proteases could help prevent plaque destabilization and formation of occlusive thrombi. Cells within atherosclerotic lesions also

express specific tissue inhibitors of metalloproteinases (TIMPs) and thus localized overexpression of these inhibitors could also be an effective gene therapy approach for cardiovascular disease.

8.3 Regulators of Vascular Tone and Blood Pressure

Elevated blood pressure is a known risk factor for cardiovascular disease. It is well established that as atherosclerotic lesions progress, the affected blood vessel loses its capacity to adequately vasodilate. Controlling acute changes in vascular tone that cause *vasospasm* may be even more fundamental to CVD as evidence suggests that vasospasm may precipitate plaque rupture and the formation of occlusive thrombi. There are currently many drugs available for chronically controlling high blood pressure but very few for managing vasospasm. Thus, localized gene therapy that targets the production of vasoactive substances by arterial wall cells or the response of smooth muscle cells to these vasoactive substances leading to increased vasodilation and reduced vasospasm may be effective approaches for the treatment of cardiovascular disease.

Nitric oxide is an extremely potent vasodilator and most endothelial cells express an endothelium specific form of nitric oxide synthase (e-NOS). However, e-NOS expression and NO production are reduced in atherosclerotic arteries. Thus, a localized increase in the expression of e-NOS could help alleviate the impaired vasodilatory properties of atherosclerotic arteries. Endothelial cells also produce the vasodilatory prostaglandin, prostacyclin (PGI_2). PGI_2 is produced from arachidonic acid by the action of the cyclooxygenases followed by PGI_2 synthase. Thus, increased expression of PGI_2 synthase could be an effective approach for increasing PGI_2 synthesis. Endothelial cells also produce a variety of vasoconstrictors such as endothelin-1 and endothelial cell hyperpolarizing factors. Thus, inhibiting expression of the proform of endothelin or the endothelin-converting enzyme that activates endothelin could help control vasoconstriction. There are also endogenous inhibitors of endothelin activation such as the endothelin-converting enzyme inhibitor that could also be locally overexpressed and play a beneficial role in regulating blood pressure. Similarly, endothelial cells express a form of the angiotensin-converting enzyme (ACE). Angiotensin-II is a potent vasoconstrictor. It is produced following the conversion of angiotensinogen to angiotensin-I by renin and from angiotensin-I to angiotensin-II by ACE. Thus, inhibition of endothelial expression of ACE could also be an effective therapy. Finally, blocking the response of smooth muscle cells to these various vasoconstrictors or increasing the response to the vasodilators by targeting expression of the specific smooth muscle cell receptors or the down stream signal transduction pathways may also be effective gene therapy targets.

8.4 Coagulation Related Genes

There are a variety of pharmacological agents that effectively inhibit *thrombosis*, and chronic administration of these drugs is associated with reduced frequencies of angina and myocardial infarction in people with established cardiovascular disease. However, because we still do not know what causes atherosclerotic plaques to rupture and because plaque rupture is

unpredictable, administration of anticoagulants throughout the three to four decades that lesions develop may not be practical for most people due to the accompanying bleeding disorders. Thus, specifically blocking the expression of procoagulant proteins such as tissue factor by cells within atherosclerotic lesions, may be an effective approach to preventing localized formation of occlusive thrombi following plaque rupture. Tissue factor participates in the extrinsic pathway of coagulation and binds to and activates factor VIIa, which in turn activates factor X enabling it to convert prothrombin to thrombin and thrombin to convert fibrinogen to fibrin, the primary protein component of blood clots. Cells within atherosclerotic lesions also express a specific tissue factor inhibitor; thus an additional possibility would be to stimulate expression of this inhibitor. Another potential approach for reducing formation of occlusive thrombi is to increase the production of thrombolytic factors such as plasmin by increasing the localized expression of tissue plasminogen activator or reducing the expression of the plasminogen activator inhibitors.

8.5 Osteogenic Proteins

Bone mineral (calcium-phosphate) is deposited in most advanced atherosclerotic plaques and in heart valves. However, it is still controversial as to whether calcification of the plaques is a good prognostic indicator of subsequent CVD events. Nevertheless, preventing vascular calcification is beneficial for interventions such as angioplasty and for reducing the need for heart valve replacement. Vascular calcification is now known to be an active cellular mediated process that is analogous to the process by which cartilage is converted to bone. It thus involves a balance between bone forming osteoblast type cells and bone removing osteoclast type cells and the expression of proteins that are both pro-osteogenic and antiosteogenic. These include the matrix gla proteins, osteopontin, osteoprotegrin, osteonectin, and the bone morphogenic proteins. Thus, localized gene therapy designed to either increase or inhibit expression of these proteins could have dramatic effects on reducing plaque calcification and complications resulting from ''stiffening'' of the blood vessels.

Keywords

Demographics
The study of populations, especially growth rate and age structure.

Effective Population Size
The size of an ideal population that would show the same rate of decay in heterozygosity as the actual population.

Electrophoresis
The movement of molecules on a solid medium through an electric field. Various support mediums are used, including filter paper, starch gel, agarose, and polyacrylamide.

Molecular Clock
The rate of molecular genetic change at a given gene, often including the assumption of a constant rate.

Polymorphism
Two or more genetically distinct types in the same interbreeding population.

1 Introduction

The molecular genetic analysis of populations involves three main stages: sample collection, analysis, and interpretation. The sample must be representative of the population, and therefore collections need to be random and sufficiently large. The number of samples analyzed is especially important when comparisons are based on allele frequencies. In each case, the allele frequency determined by the sample will be an estimate, and the 95% confidence limits around that estimate depend on the sample size as follows:

$$p \pm 1.96\sqrt{\frac{p(1-p)}{n}}$$

where p is the allele frequency and n is the sample size. For example, for an estimated allele frequency of 55%, the 95% confidence limits around that estimate would range from 33 to 77% for a sample of 20 and from 45 to 65% for a sample of 100.

The method of molecular analysis and choice of genetic marker will depend on the specific question being addressed, although in general it is advantageous to assess diversity at a number of independent loci. Interpretation of results will depend in part on the method of analysis. DNA analytical methods offer great potential through the analysis of specific regions of the nuclear, mitochondrial, and chloroplast genomes, but numerous evolutionary mechanisms can effect change over time, and therefore interpretation based on time-dependent change must be done cautiously. An understanding of the genetic structure of populations facilitates the understanding of dispersal, reproductive, and social behavior, and provides essential data for the conservation of natural variation.

It has long been recognized that inherited characters vary and that the quantification of this variation can be used to distinguish local races. However, it was not until the advent of protein gel electrophoresis in the 1960s that the extent of genetic variation in natural populations began to be appreciated. Thousands of species have been investigated for protein polymorphisms, and most displayed extensive variation. Gel electrophoresis of allozymes (different electrophoretic forms of a given enzyme) became the standard method for the comparison of genetic variation within and between populations, and it is still in use today. However, most of the variation present in the genome cannot be detected by this method. The DNA sequence determines, through an RNA intermediary, the amino acid sequence in the polypeptides that combine to form proteins. Only a small proportion of the genome is translated into proteins, and the three-letter codon that determines the sequence of amino acids is degenerate, especially in the second and third positions (see Sect. 2). Therefore, even within the DNA sequence that encodes the protein, there can be considerable variation that is not expressed. Furthermore, only a small proportion of the changes that do affect the amino acid sequence will also affect the charge properties of the protein, which determine its migration through an electric current (and consequently only some changes can be detected by the electrophoretic method). Innovations over the last several decades have enabled the analysis of DNA directly, providing greater resolution and facilitating the interpretation of variation. This article concentrates on the use of these DNA analytical methods to interpret population-level genetic variation.

2 Nature of Mutations and Mutation Rates

Mutations that affect the sequence of nucleic acids can occur through the conversion of a single base (e.g. a point mutation changing A to T), through the loss by deletion of one or more bases, and through the addition by insertion of one or more bases. Change can also occur through the operation of a variety of DNA ''turnover'' mechanisms. For the purpose of this discussion, two mechanisms that generate variation in repetitive regions of DNA by changing the number of repeated elements will be emphasized. These are DNA slippage (Fig. 1a) and unequal crossing-over (Fig. 1b). In each case, a misalignment of DNA strands causes the molecule to be repaired in such a way that there is a gain or loss in an array of repeated elements. Repetitive DNA regions are very common in most vertebrate and plant genomes, and change in the copy number of repeats generally occurs at a much higher rate than change due to point mutations. For this reason, they provide high resolution to population genetic analyses and are often used.

Eukaryotic genes are divided into coding (exons) and noncoding regions (introns). Introns are transcribed into RNA, but not translated into proteins (Fig. 2), which means that these sequences are not phenotypically expressed. Point mutations accumulate at a higher rate in noncoding regions, in part because of a diminished level of selection. Within coding regions, the second or third position of the codon is often ''synonymous''; that is, the nucleotide in those positions can change without changing the encoded amino acid. For the nuclear genome of eukaryotes, the nucleotide substitution rate (per base pair, per year) in introns

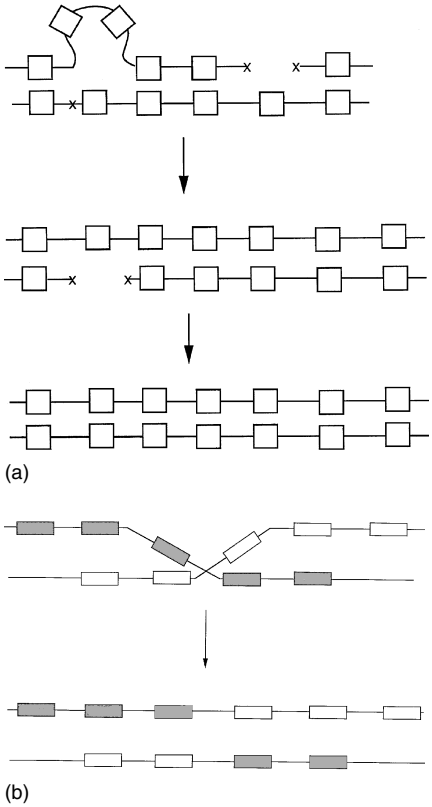

Fig. 1 (a) One of several possible DNA slippage mechanisms: the end result is an extension of the array within a single chromatid. Similar mechanisms lead to contraction of the array or slippage during replication. The process illustrated involves endonuclease-mediated breakage, slippage of the upper strand, and polymerase-mediated repair events. The boxes represent repeated elements. (b) Unequal crossing-over. Two strands, each with five repetitive elements, undergo an unequal crossing-over event, resulting in the gain of one element for the upper strand and a corresponding loss from the lower strand.

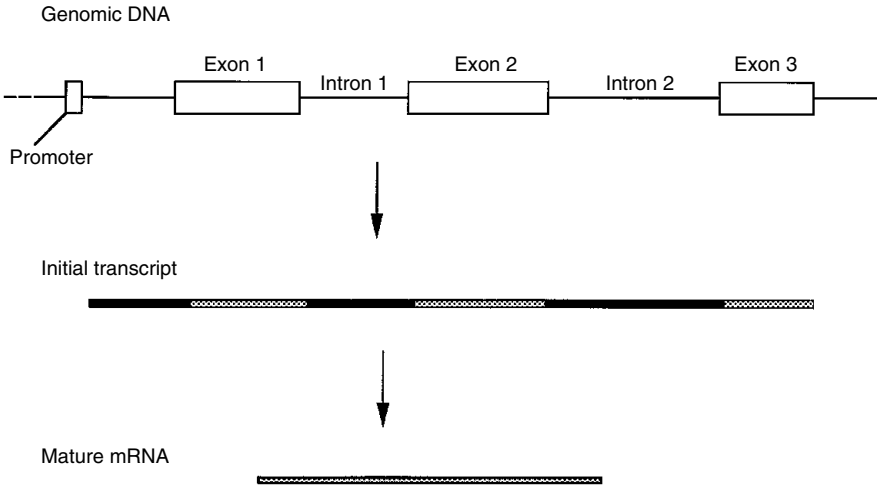

Fig. 2 Division of genes into coding (exons) and noncoding (introns) regions. The initial transcript is enzymatically modified to represent only the exon regions of the gene in the mature messenger RNA.

and synonymous sites ranges from about 1×10^{-9} to 10×10^{-9} with an average of about 5×10^{-9}. In exons, the rate varies from about 0.004×10^{-9} in histone genes to 2.8×10^{-9} in interferon A. Natural selection (see Sect. 3.1) usually prevents major disruption of coding sequences with repetitive DNA regions (though there are exceptions such as the FMR1 locus), but this is a common feature of noncoding regions. The rate of DNA turnover in these repetitive sequences depends on which mechanisms are affecting change and various other factors. The rate of change due to these processes can be very fast; rates up to 10^{-2} have been documented.

3 Dissemination of Genetic Change in Natural Populations

Natural selection and genetic drift are the two principal mechanisms by which genetic change is spread through a population. The correct interpretation of genetic variation depends on how the DNA region under analysis is affected by each of these mechanisms. Although it is beyond the scope of this article to provide a detailed discussion, the basic tenets are outlined below.

3.1 Natural Selection

The biochemical, morphological, physiological, or behavioral consequences of genetic makeup (*genotype*) are referred to as the *phenotype*. Natural selection is the differential reproductive success of different phenotypes. Generally, if a region of DNA is not expressed phenotypically (nor affected by or closely linked to a phenotypically expressed region), it is not exposed to natural selection. On the other hand, some genes are critical to survival or reproductive success and therefore are under strong selective control. A simple model for the change in allele frequency due to selection in a two-allele system for a diploid organism can be expressed as follows:

$$p' = \frac{p^2 w_{11} + pq w_{12}}{W}$$

where p' is the frequency of allele A_1 after selection, p is the frequency of A_1 before selection, q is the frequency of A_2 before selection, w_{11} is the viability of the homozygous genotype A_1A_1, w_{12} is the viability of the heterozygous genotype A_1A_2, and W is the average viability. From this relationship, it is possible to derive the expected change in allele frequency over time due to selection and make predictions about the dynamics of natural selection under different environmental conditions.

Genetic variation at a locus can be maintained in a population by balancing selection such as overdominance (when the heterozygote condition is selected for) and frequency-dependent selection, or limited by directional selection (when one allele is favored at the expense of the others). Adaptation to specific habitats and the general character of the local environment can also affect genetic diversity. For example, it has been proposed that habitat specialists might be expected to show lower levels of genetic diversity than habitat generalists, and species inhabiting relatively stable environments might be expected to show low variability. In each case, the prediction is based on the idea that a more complex or variable environment will support a greater degree of genetic variation within the population as a whole.

3.2 Genetic Drift

Genetic drift is the random changes in allele frequency over time in finite populations, resulting from variation in the number of offspring among individuals. According to the "neutral theory," most evolution occurs through the random fixation of selectively neutral (or slightly deleterious) mutations. This theory predicts that change accumulating in this way will do so at an approximately constant rate (a molecular clock). When this is true, genetic change can be used to interpret the demographic histories of populations. Figure 3 plots the expected relationship between effective population size, genetic diversity, and the time (in generations) required for lost variability to be recovered.

The relationship between diversity (expressed as heterozygosity) and population size can be expressed as follows:

$$H_t = H_{t-1}\left(1 - \left(\frac{1}{2N_e}\right)\right)$$

where H_t is the heterozygosity in generation "t," H_{t-1} is the heterozygosity in the previous generation, and N_e is the effective population size. In general, diversity is lost more quickly in small populations owing to the greater likelihood of sexually recombining alleles that are identical by descent (inbreeding).

Stochastic events (such as a population bottleneck) can also reduce variation in a population. The result is a small population in which the effects of genetic drift are expected to reduce levels of variation, both as a consequence of the

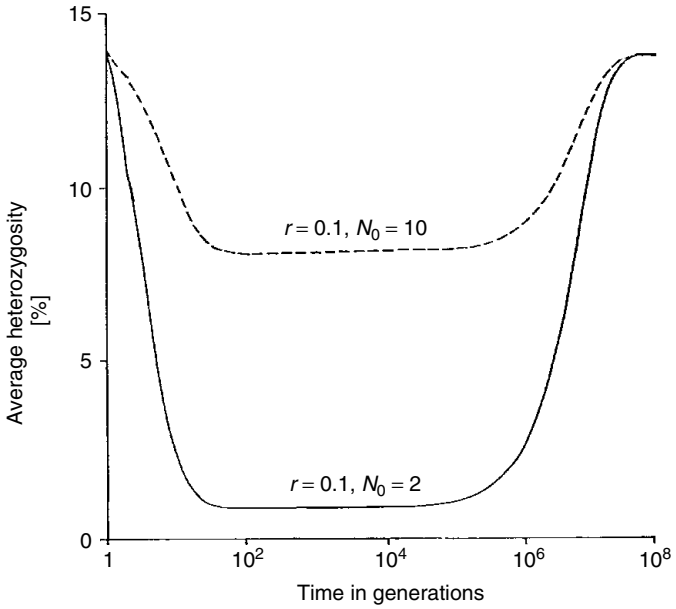

Fig. 3 The theoretical changes in average heterozygosity when a population goes through a bottleneck. Logistic growth is assumed, and the intrinsic rate of growth r is set at 0.1. In one case (solid line), the bottleneck effective population size is $N_0 = 2$; in the other (dashed line) $N_0 = 10$ [After Nei (1987)].

sampling of genotypes (and the resulting loss of allelic diversity) and by inbreeding (as described above). Once variation has been lost, the process of accumulating new mutations is very slow (Fig. 3). An equilibrium level of variation will take on the order of the inverse of the mutation rate to recover, which is in some cases longer than the expected lifespan of the species.

4 Methods of Analysis

There are numerous methods by which genetic variation can be directly or indirectly measured. This article concentrates on those methods that have been fundamental to population genetic studies, now and historically. The evolutionary history of a given gene can be affected by various processes including selection and drift, and provides just one record in the study population. For this reason, it is important to investigate variation at as many loci as practical, so that information on the history of the population can be accumulated, rather than simply the history of a gene in that population. At the same time, there can be some utility to choosing markers of a particular level of polymorphism to facilitate different types of analyses. For example, a marker that evolves relatively slowly but is thought to be selectively neutral would allow a relatively unambiguous assessment of the phylogenetic relationship between distantly related taxa. At the other extreme, hypervariable markers such as microsatellite or minisatellite arrays (see Sect. 5) can be used to assess paternity and close kinship relationships. For comparisons among populations, too much variation will obscure genetic differences (saturation will lead variation within a population to be as great as that between populations), and too little variation will not permit sufficient resolution. Repetitive DNA regions can vary in the rate of change over time over a very broad spectrum, owing to the nature of the processes involved. The comparison of these loci therefore needs to take this potential rate heterogeneity into account.

4.1 Sample Collection

Essentially, any cellular tissue is suitable for the extraction of DNA (see Sect. 4.3), though it some tissues (such as bone or wood) are harder to extract DNA from than from others (such as skin or leaves). The choice of tissue for enzyme electrophoresis (see Sect. 4.2) may be restricted by which enzyme systems are expressed in different tissues. The first step in any project is to define the objectives and plan what can be accomplished on the basis of time and budget. In most cases, it will be more important to include multiple loci than very large numbers of individuals; however, small sample sizes risk low power (see below) and distortion of allele frequencies due to sampling effects. The analysis of a large number of loci helps minimize the impact of locus-specific effects, such as selection, as indicated in the previous section. Some applications will require a choice among types of loci, for example, tests for biparental kinship require nuclear loci and high resolution, and the obvious choice becomes microsatellite loci (see Sect. 5.5).

There are two types of error in the relevant statistical comparisons among populations. A type I error occurs when a null hypothesis that should be accepted is rejected. In biological studies, the allowance for this type of error is often

set at 5%, though a more stringent criterion should be adopted if a large number of comparisons are done. A type II error occurs when a null hypothesis that should be rejected is accepted. This is usually expressed as the power of the test, which is 1 minus the type II error. For a comparison between two populations using just one marker, with a difference of 5% between allele frequencies, thousands of individuals would need to be screened to statistically distinguish between them, given a type I error of 5% and a power of 90%. The solution is to use more markers with an emphasis on those with a high level of variability. Typically, it will be sufficient to represent each population with a random sample of at least 50 individuals and compare putative populations at 10 to 20 polymorphic loci.

The collection of samples will depend to some extent on the biology of the study species. In mobile, sexually reproducing species, the dispersal behavior of males and females can affect the distribution of genotypes. For example, if females are phylopatric (reproducing rear where they were born), genetic variation between adult males and females in local samples may vary. Furthermore, in this case, the comparison of populations using a matrilineally inherited marker (such as mtDNA in mammals) will exaggerate the difference between populations. It is also important to take into account temporal and spatial patterns of movement in mobile species. A project that begins sampling in one location and finishes in another sometime later might simply follow the migration of a single reproductive population! With plant species, it is important to consider the dispersal of both pollen and seeds, and the possibility that seeds ''bank'' in the soil, providing a reservoir of genetic material from previous generations.

4.2 Enzyme Electrophoresis

The migration of proteins through an electric field in a gel matrix can be measured by enzyme electrophoresis. The charge properties of the protein determine the extent and direction of migration. The different electrophoretic forms of the enzyme are known as allozymes. Tissue homogenized in buffer can be used as the source material, and specific enzymes can then be visualized by immersing the gel into a medium containing the reaction conditions for that enzyme such that a colored dye is incorporated into the end product. The dye produces bands on the gel indicating the position of the enzyme. The number of bands will depend on the number of subunits in the enzyme and on whether the locus is homozygous or heterozygous. Gels can be prepared from a variety of media (starch, polyacrylamide, agar, etc.) and run by a variety of methods (horizontal, vertical, disc, etc.). For screening large numbers of individuals in a population survey, the most common method (also the simplest and least expensive) is horizontal starch gel electrophoresis. The apparatus for this method is schematized in Fig. 4. Gels running 10 to 30 samples can be cut horizontally 2 times (giving 3 slices) and each slice stained for a different enzyme. In most cases, the resolution of bands is sufficient, and poor resolution can often be improved by using a different gel medium or running method. In general, the different methods are designed to improve resolution and to permit the separation of more subtle differences between alleles.

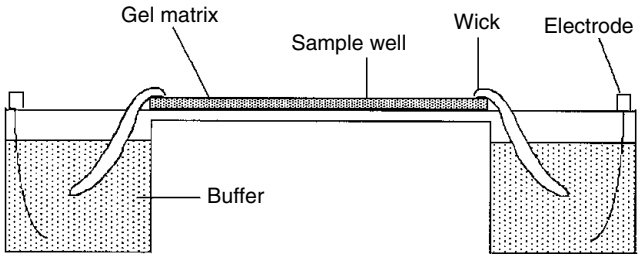

Fig. 4 Nondenaturing horizontal gel electrophoresis of proteins.

4.3 DNA Extraction

DNA is extracted from tissue by removing proteins, fats, and carbohydrates and then precipitating the DNA out of an aqueous salt solution. This procedure is usually straightforward for animal tissues, but it can be quite difficult with plant material because naturally occurring chemicals degrade the DNA or inhibit further analysis. The first step is to homogenize the tissue under an aqueous-based buffer that promotes cell lysis. By the most common method (Fig. 5), the homogenate is mixed with phenol and chloroform, which are immiscible with water. The proteins and other cellular compounds go into the organic (phenol) phase, while the DNA remains in the aqueous phase. After several repetitions, the DNA is precipitated with salt and ethanol. A careful preparation of DNA will include sheared fragments 20 to 100 kb long. Excessive agitation

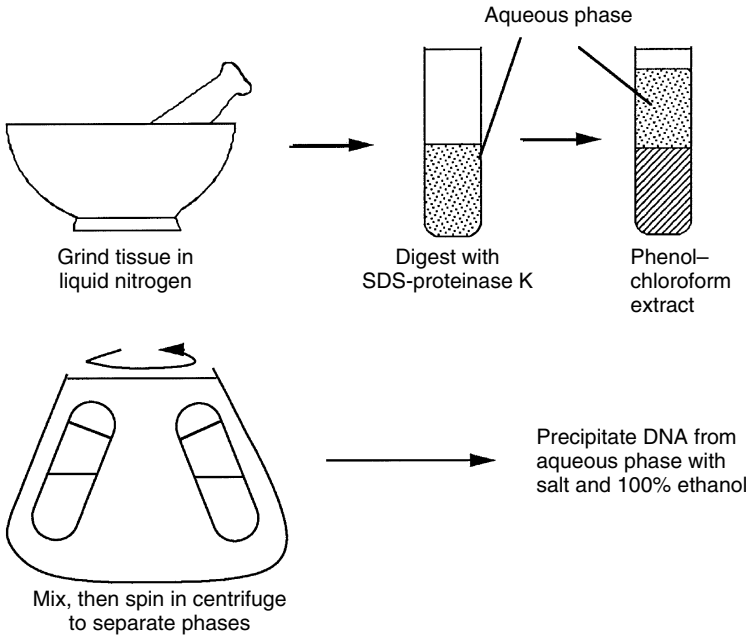

Fig. 5 Phenol–chloroform extraction of DNA from solid tissue.

further shears (degrades) the DNA. Since nucleases (which can be present on the fingers and particulate matter in the air) will also degrade DNA, the procedure must be done under sterile conditions.

4.4 RFLP Analysis

Restriction fragment length polymorphisms (RFLPs) can be analyzed when DNA is digested with a special enzyme called a *restriction endonuclease* (Fig. 6). These enzymes recognize specific short sequences of DNA (e.g. the enzyme *Eco*RI recognizes the sequence GAATTC) and cleave the DNA at every instance of that sequence. Mutations that create new sites or eliminate old ones can occur. The next step is to separate the DNA fragments by size in a gel matrix. This is done by electrophoresing the samples through an agarose or polyacrylamide gel under buffer. DNA naturally assorts by size (on a roughly logarithmic scale) by this method. The double-stranded DNA in the gel is then made single-stranded (usually with an alkaline solution) and is transferred by "Southern blotting" onto a solid membrane that binds DNA (Fig. 7). Then, a segment of DNA to be compared between individuals (e.g. the *Adh* gene or the mitochondrial genome) is labeled with a radioisotope (or some nonradioactive label) and hybridized (whereby complementary strands of DNA combine and re-form a double-stranded molecule) to the DNA bound to the membrane. Only the fragments of bound DNA that match this DNA probe will be made radioactive. After exposure to X-ray film, these relevant fragments can be visualized as black (exposed) bands on the film (Fig. 8). Now that DNA sequencing (see Sect. 4.5) has become routine and affordable, RFLP analysis is used less frequently for population studies.

4.5 DNA Sequencing

The procedure that determines the sequence of nucleic acid bases comprising

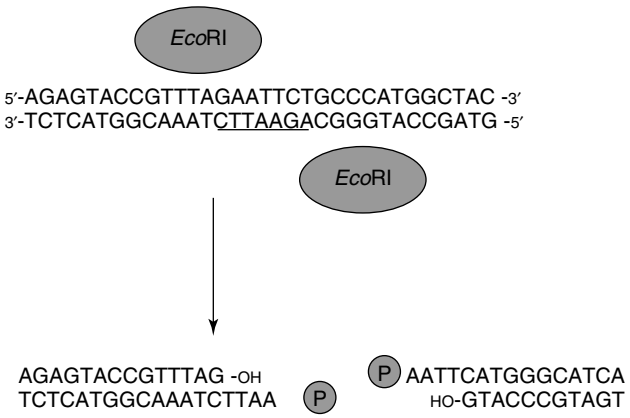

Fig. 6 Restriction digestion with the enzyme *Eco*RI. Digestion leaves a 3′ hydroxyl group and a 5′ phosphate group exposed, and either a 5′ overhang (shown), a 3′ overhang, or blunt ends, depending on the enzyme. *Eco*RI has a 6-bp recognition site. Many other common enzymes have 4-bp recognition sites.

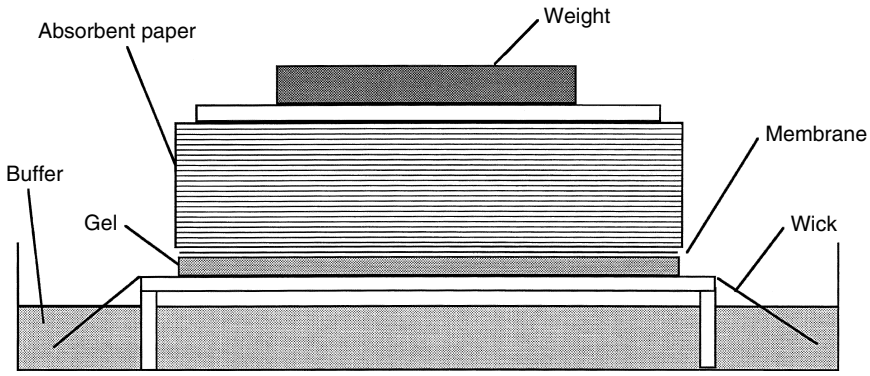

Fig. 7 Southern blotting to transfer DNA from gel to membrane.

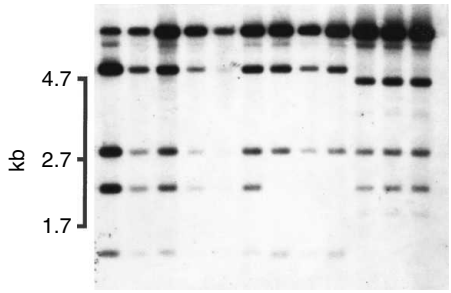
Fig. 8 Panel of 12 lions digested with *Ava*II and hybridized with a heterologous mtDNA probe. (Courtesy of Robyn Hottman and Steve O'Brien.)



a segment of DNA offers the greatest resolution for comparisons of genetic differentiation and permits the greatest scope for interpretation. There are several methods of DNA sequencing, but the one used most frequently is chain termination. By the chain termination method, a single-stranded DNA template is divided into four reaction mixes, one for each nucleotide base (A, T, C, G). A DNA polymerase (an enzyme that can synthesize DNA along a single-stranded template, starting at a double-stranded/single-stranded interphase), a short (15–25 bases) primer segment of DNA, and all four deoxynucleotide bases are included in each reaction (one of which is labeled either radioactively or with a fluorescent dye). In addition, each reaction will include a smaller quantity of one of the four dideoxynucleotides (A, T, C, or G). These bases lack the 3′-OH group (Fig. 6) necessary for DNA chain elongation and therefore terminate the reaction at every occurrence of that base. A comparison of the length of strands synthesized for each of the four reactions gives the sequence of bases (Fig. 9). Modern sequencing is facilitated by the polymerase chain reaction (see Sect. 4.6) and visualized by computer-generated profiles that display a series of peaks, each representing a different nucleotide labeled with a different fluorescent dye. This allows for very rapid analysis as the sequencing machine generates a computer file of the sequence as the DNA runs through the gel. It also permits the running of all four sequencing reactions (one for each nucleotide) in a single lane, since each is labeled with a distinct dye.

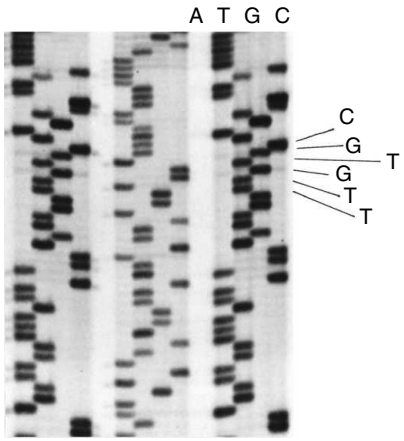


Fig. 9 A small portion of the nucleic acid sequence that can be "read" from a gel subjected to the chain termination method. The four reactions (one for each nucleic acid residue) are run side by side on a 6% polyacrylamide gel.

4.6 PCR Analysis

The polymerase chain reaction (PCR) permits the enzymatic amplification of a specific segment of DNA. This technique has greatly facilitated population-level screening of genetic variation by saving time and reducing expense. Two short primers of single-stranded DNA (usually 15–25 bases long) are designed flanking a region of interest. These are often based on published DNA sequences of particular genes or are developed from cloned DNA. A programmable heating block is then used to vary the reaction conditions. First the reaction mix is heated to denature the template DNA (to separate the double helix into its two complementary strands); then the temperature is lowered to allow the primers to anneal to the template, the reaction mix is heated to an optimal temperature for the polymerase, and the cycle is repeated 20 to 40 times (Fig. 10). The key to this technique is the use of a thermostable polymerase (most polymerases would be denatured and rendered inactive by the high temperatures necessary for the DNA denaturation step).

4.7 SSCP and Gradient Gel Analysis

Single-strand conformation polymorphisms (SSCPs) are based on the sequence-dependent mobilities of denatured (single-stranded) DNA when run through a nondenaturing gel. PCR-amplified DNA, usually 100 to 200 bp long, is denatured and loaded onto a gel in nondenaturing conditions. As the molecule migrates through the gel, it reanneals with itself, folding into a hairpin structure. The conformation and mobility of this structure depend on the sequence of DNA residues. As little as a single base change in 200 can alter the distance a fragment will migrate in the gel, although there is no simple correspondence between sequence composition and mobility. Therefore, differences can be detected quickly (permitting the screening of a large number of samples simultaneously), but they must be quantified by sequencing all products with distinct mobilities.

Gradient gel electrophoresis, an alternative method for detecting single base changes, is based on the melting (denaturing) properties of DNA in solu-

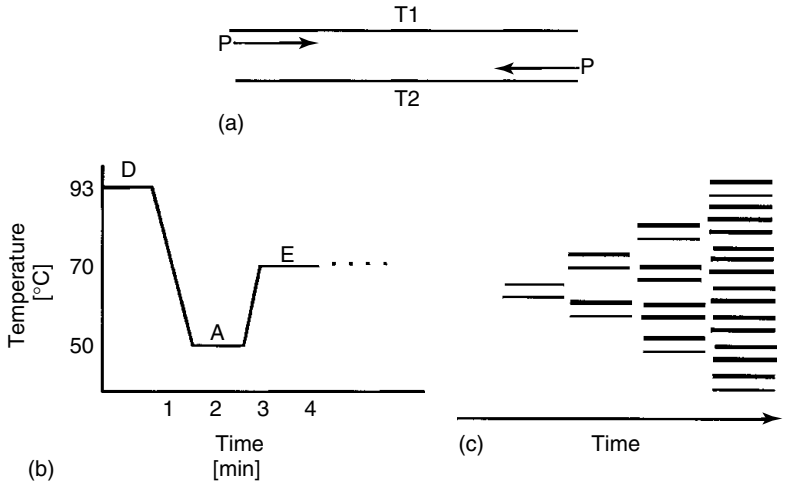

Fig. 10 The polymerase chain reaction (PCR). (a) Short oligonucleotide "primers" anneal to the denatured template DNA. (b) The reaction is cycled between denaturing, annealing, and extension temperatures. (c) Repeated cycling results in an exponential amplification of the target sequence.

tion. DNA melts in domains of two dozen to several hundred base pairs. Sequence changes within a domain are characterized by mobility changes. As the double-stranded molecule passes through the denaturing gradient, it becomes increasingly denatured, and its mobility reflects the sequence within each melting domain. Changes within the last domain would not normally be detected because sequence-dependent migration is lost upon completion of strand dissociation. To correct for this degradation, a 30- to 40-bp GC-rich sequence (a "GC-clamp") is added to the 5′ end of the PCR primers used to amplify the sequence being analyzed.

4.8 RAPD Analysis

Random amplified polymorphic DNA (RAPD) analysis uses just one short oligonucleotide (usually 10–12 bp) in a PCR reaction to amplify random segments of DNA. It works because a small number of fragments (5–10) will be amplified when the oligonucleotide anneals by chance on each template strand over a size range that can be amplified by PCR (usually about 3 kb). A 10-mer, for example, will anneal by chance once every million base pairs (about a thousand times in the human genome). There are two ways by which the amplified fragments can show polymorphisms. First, the amplified region may be repetitive and show length variation in the population (i.e. there will be a variable number of tandem repeats: VNTR). In this case, the relevant band will show a size variation, although very large alleles may not amplify (PCR preferentially amplifies smaller fragments). Second, a single base-pair polymorphism may interfere with the annealing of the primer in some individuals. In this case, the band will be present or absent, but if present, it is not expected to vary in size.

5
Choice of Genetic Marker and Interpretation

The nuclear genome is a mosaic of DNA regions under the influence of different mechanisms affecting change, and it is conserved by selection to different degrees. In addition, there are the mitochondrial genomes and, in plants, the chloroplast genomes, with their own unique properties. A population geneticist can use this variation in the mode and rate of evolution to advantage, but it also means that results must be interpreted cautiously. Six types of genetic marker are described here, each with different properties and, in some cases, best suited to particular levels of analysis.

5.1
Allozymes

Enzymes are a functional part of cell physiology and are therefore exposed to natural selection. The apparent rate of evolution in these markers varies greatly, from about 10^{-9} to 10^{-6} change per gene (given an average length of 1,000 bp) per year. In some cases – for example, in the histone genes – there is clearly strong selection, which would need to be considered when population patterns are interpreted. However, studies have shown that even in coding regions, the evolutionary rate is often relatively constant over time, and therefore allozyme polymorphism can be useful for assessing the differentiation of populations by drift. As described in Sect. 4.2, the analytical procedure (enzyme electrophoresis) is relatively fast and inexpensive; however, the level of resolution possible is relatively low, because only a small proportion of the total variation in a gene is expressed or detectable by electrophoresis (see Fig. 2 and Sect. 5.2).

The data generated by this method are for the most part Mendelian, and the patterns resulting from segregation at a single locus can usually be distinguished. This means that data can be interpreted with respect to theoretical predictions about the frequency of genotypes in a population, based on the frequency of alleles. Deviations from the expected frequency (as predicted by Hardy–Weinberg; see Sect. 6) can be quantified statistically and interpreted. Furthermore, knowing the function of the encoded protein can help with the interpretation of patterns of variation and deviations from expected frequencies. For example, an excess of heterozygotes could indicate selection for heterozygotic individuals (heterosis), while an excess of homozygotes could indicate inbreeding or directional selection. Knowledge of the gene product could help determine the likely factor. When the data are consistent with Hardy–Weinberg expectations, formulations to interpret genetic distance and relative levels of variation can be applied (see Sect. 6).

5.2
Nuclear Genes

Sequence data of nuclear genes, including those encoding enzymes, offer an immediate advantage over enzyme electrophoresis. This is because coding and noncoding regions can be differentiated, and within the coding region of the gene, synonymous and nonsynonymous sites can be distinguished. Thus, regions that are likely to be under the influence of natural selection can be separated from those that are more likely to be evolving at a neutral rate. It also becomes possible to compare sequences and to determine the

mode of mutation (point mutation, deletion, insertion, rearrangement, etc.), and in some cases, the mechanism. All these factors contribute to the accurate interpretation of the observed variation.

For comparisons between conspecific populations, it is necessary to identify both alleles for each individual, and this is typically more difficult in nuclear DNA sequencing than in enzyme electrophoresis because of the need to sequence a number of clones from each individual to ensure that both alleles have been sampled. One relatively easy way around such detailed sequencing is to screen the population using either the SSCP or gradient gel methods. These methods identify sequences that are distinct by as little as one base pair. In most cases, a single locus will show two bands when heterozygous and one when homozygous (although sometimes there are repeatable artifact bands related to additional stable conformations of the single strands). Combined with DNA sequencing to distinguish the different phenotypes indicated by SSCP or the gradient gel, this approach provides an efficient and very powerful protocol for the screening of variation at the population level. It shares most of the advantages of allozyme electrophoresis (apart from considerations of difficulty and expense) and provides considerably greater resolution.

Variation in nuclear genes can also be quantified using the RFLP method, which permits the rapid screening of a large number of samples. RFLP is limited, however, in that the precise character of the variable restriction sites is not known (unless the region has been sequenced and the sites can be mapped), and the allelic relationship at a locus cannot always be readily determined. Another consideration is the effect of methylation, to which some restriction enzymes are sensitive. Methylated sites are not cut by sensitive enzymes. This property originally evolved in bacteria as a defense against restriction enzymes produced by bacteriophage. Especially in the nuclear genome, some sites may be methylated, potentially creating within or between populations an RFLP that does not reflect a real sequence difference.

5.3 Mitochondrial DNA

In multicellular animals, the mitochondrial genome is a double-stranded, closed-circular molecule ranging in length from 15.7 to 19.5 kb. It evolves at a higher rate than comparable nuclear genomic regions (5–10 times faster; Fig. 11) and in most cases shows strict maternal transmission (no paternal contribution to the F1 generation). These two factors have made mitochondrial DNA (mtDNA) an attractive marker for the genetic comparison of animal populations. Higher levels of variation permit greater resolution, and the lack of sexual recombination facilitates interpretation. In plants the transmission is matrilineal, but the level of variation is generally very low.

Variation across the mitochondrial genome is heterogeneous, as a result of varying levels of sequence conservation, and in the ''control region,'' DNA slippage. A common and very useful method of analysis is to sequence mtDNA regions that have been amplified by PCR. Sequences of up to 1,000 bp can now be routinely amplified and sequenced, and this is now the most common method of analysis.

Demographic considerations are important to the interpretation of mtDNA variation for two main reasons. First,

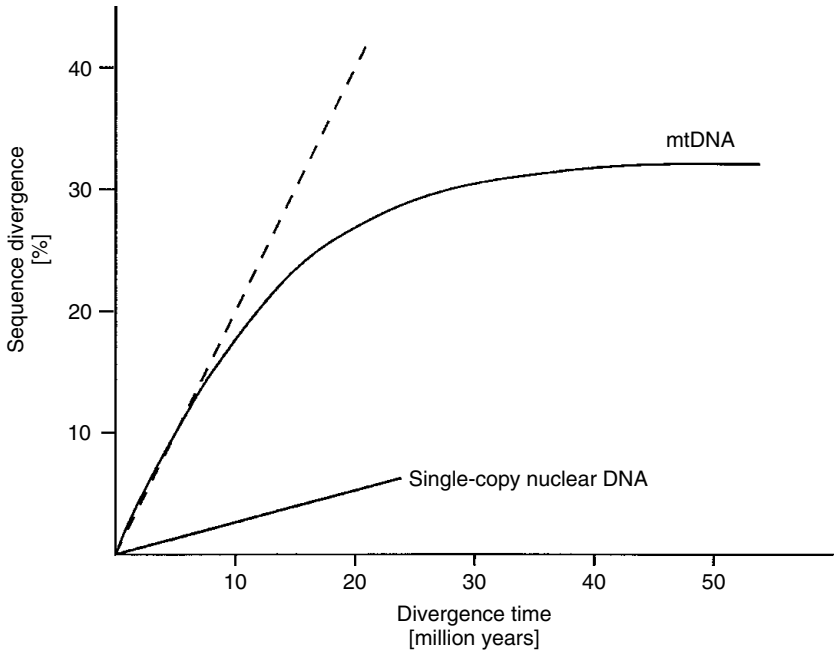

Fig. 11 Rates of nucleotide substitution in single-copy nuclear DNA and mtDNA, plotted with the theoretical rate without saturation effects in mtDNA (dashed line). [After Brown et al. (1979) in Hoelzel and Dover (1991).]

mtDNA is more labile to extreme fluctuations in population size than nuclear DNA, since a single mating pair will pass on four copies of the nuclear genome but only one copy of the mitochondrial genome. Also, the local extinction of matrilines can limit the diversity of mtDNA, especially in small populations. Second, the geographic distribution of mitochondrial haplotypes will depend on the dispersal behavior of females. If females are less likely to disperse (as is commonly the case for mammals), then mtDNA variation may show greater geographic structuring than nuclear DNA variation. Interpretation can also be complicated by the existence of more than one form of the mitochondrial genome in an individual, but this condition (heteroplasmy) is relatively rare.

5.4 Chloroplast DNA

Sequence variation in the chloroplast genome (cpDNA) is highly conserved, as is variation in the size of the genome for most taxa, though the range for all plant species is large (120–217 kb). Inheritance can be biparental, strictly maternal, or strictly paternal depending on the species. Most population studies have found very low levels of cpDNA variation, though there are exceptions. The utility of this genome as a population genetic marker will depend on the mode of transmission and level of variation for a given taxa. Strict paternal or maternal transmission may provide useful information even if the relative level of variation is low.

5.5
Minisatellite DNA

There is an abundance of repetitive "satellite" DNA in the nuclear genome of most complex organisms. These regions are classified according to their composition and structure. Minisatellite arrays are nested repeats of a highly conserved core sequence, 15 to 40 bp long, interspersed on most chromosomes. A minisatellite array can be up to 20 to 25 kb long. A high rate of unequal crossing-over generates a high level of length variation in these arrays. The "DNA fingerprinting" method took advantage of the conserved minisatellite core sequence and the large number of loci sharing that core repeat. A probe for the core sequence was used in a multilocus RFLP analysis, which reveals a ladder of hypervariable bands that could identify an individual or determine paternity with a very small chance of error (Fig. 12). While DNA fingerprinting is a powerful

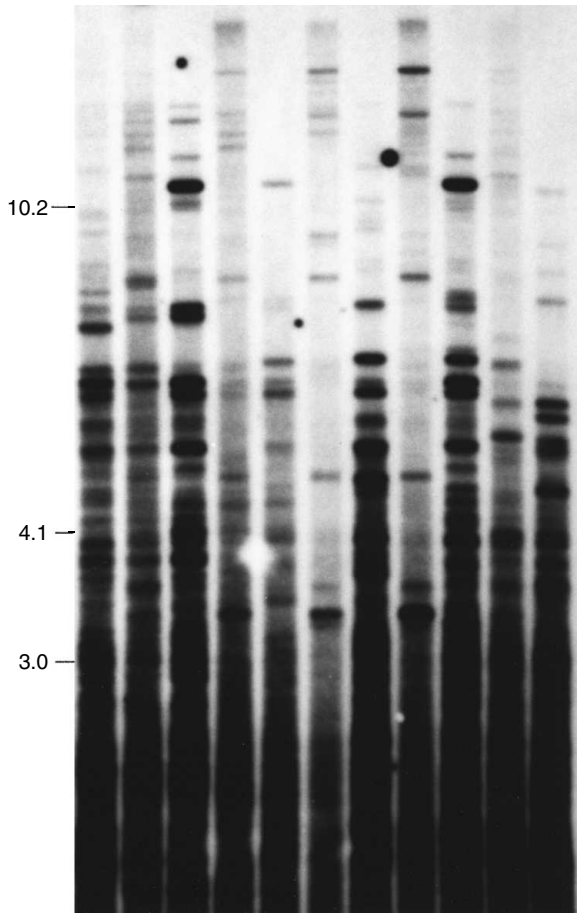

Fig. 12 Minisatellite DNA variation (DNA fingerprints). DNA from 11 southern elephant seals was digested with *Hae*III and probed with (CAC)*n*. Fragment sizes shown in kilobases.

tool for the assessment of close kinship, the interpretation of variation in this marker at the population level is not straightforward. One problem is that variation saturates such that variation within a population is often as great as variation between populations. This marker is typically more useful to a population geneticist as a tool to reveal reproductive strategy, which in turn has an important effect on the genetic structure of a population.

Exceptions to this general rule exist, especially when genetic variation for a population or species has been reduced. In this case, variation for the multilocus pattern must be statistically treated as a phenotype, since the allelic relationship between bands in the fingerprint cannot be determined in most cases. Typically, a relative measure of ''band-sharing'' is used as an index of genetic relatedness. An alternative is to clone an individual locus and use that DNA as a probe. Single-locus minisatellite length variation can be treated as a Mendelian character, although interpretation of levels and patterns of variation should be tempered by the understanding that various mechanisms (e.g. unequal crossing-over and slippage) may promote change at different rates. It should not be assumed that these rates are constant over the relevant time frames for population-level comparisons.

5.6 Microsatellite DNA

Microsatellites are small arrays (typically about 100 bp) of simple di- and trinucleotide repeats (longer repeat elements are less common). These arrays vary in length over time because of DNA slippage (Fig. 1). The rate of change varies considerably among loci, but some are hypervariable like minisatellite loci. They are visualized by designing oligonucleotide primers on either side of the array and amplification by PCR (see Sect. 4.6). A radioactive or fluorescent label is incorporated during the amplification, typically by labeling one of the primers. The amplification products are then run on a long polyacrylamide gel (to allow single base-pair resolution), and each individual should be represented by one (homozygote) or two (heterozygote) bands (Fig. 13). Polymerase slippage during amplification usually creates artifact bands. Screening for microsatellite DNA variation is often done using fluorescent labels and a DNA sequencing machine (see Sect. 4.5). This

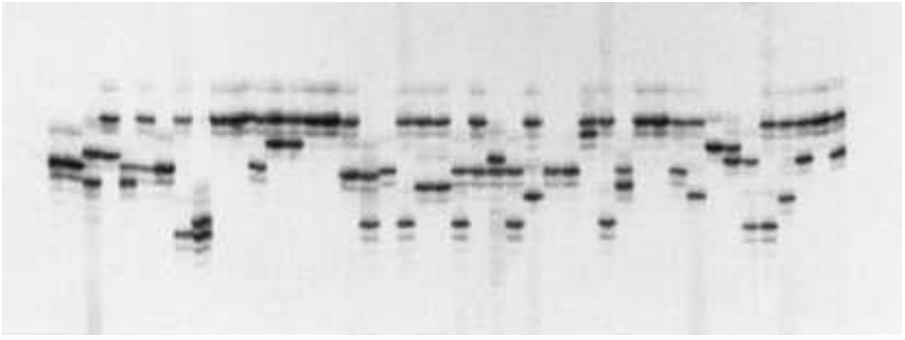

Fig. 13 Microsatellite DNA variation for 45 southern elephant seals.

allows the simultaneous running of multiple loci in a single lane (using multiple dyes) and computer-generated genotype data that can be precisely sized and compared using internal lane size standards.

Microsatellite DNA is especially useful for kinship assessment and paternity analyses, because a single locus is amplified at a time, and therefore Mendelian expectations and interpretation can be tested and applied (unlike multilocus DNA fingerprinting; see Sect. 5.5). Application at the population level is extremely common, though there are some important considerations for interpretation. These include recognition of the broad range of evolutionary rates among loci and the potential for rates to change over evolutionary time (e.g. with the accumulation of a mutation that interrupts the repetitive array and therefore the process of DNA slippage). However, the main consideration is the evolutionary model. Genetic distance measures are often assessed under the assumption of ''infinite alleles,'' which means that a new mutation should be considered novel. Given sufficient evolutionary time, this assumption is violated for sequence data (and distance measures have been derived to account for this; see Sect. 6 and Fig. 11), since there are only four nucleotides in the genetic code. Over time ''back mutations'' occur, which can lead to the underestimation of evolutionary change (see Sect. 6). This is likely to happen more frequently with microsatellite DNA loci, both because of the high rate of change and because of the nature of the change. Different alleles represent different numbers of repeats in the array, and the process of slippage can either add or remove repeats over a finite range for a given locus. Therefore, back mutation is quite likely. Interpretation of genetic distance at this type of locus therefore requires a different evolutionary model, referred to as the *stepwise mutation model*, whereby evolution is assumed to occur in steps.

6 Statistical Analysis of Variation

A full mathematical description of the statistical methods for assessing and comparing levels of variation within and between populations is beyond the scope of this article (for reviews see Nei 1987 and Hartl 2000). However, I will briefly describe a few of the general ideas and some of the assumptions on which these analyses are based. For genetic changes that are selectively neutral, the accumulation of change can be interpreted to estimate time-dependent differentiation within and between populations. For the analysis of DNA, a statistical interpretation is generally based on the following assumptions: (1) that nucleotides are distributed randomly in the genome, (2) that variation arises solely by base substitution, (3) that substitution rates are the same for all nucleotides, and (4) that all relevant bands on a gel can be detected, and similar bands are not scored as identical.

The fourth condition can be controlled by careful methodology. The first three conditions do not strictly hold, but Nei (1987) has argued that small deviations will not significantly alter the results. Also, since there are only four bases in the genetic code, there is a certain probability that mutations will revert (e.g. from A to T then back to A). Formulations have been derived to compensate for this effect (see review in Nei 1987). Allozyme variation is measured phenotypically (as the electrophoretic mobility of proteins). Therefore, it is especially important to establish that these characters follow the Mendelian rules of segregation

during sexual recombination. This is usually done by conducting pedigrees or, when this is not practical, by testing for correspondence to the Hardy–Weinberg rule (which states that the gene and genotype frequencies will remain constant between generations in an infinitely large, random mating population). This rule is expressed as follows:

$$p^2 + 2pq + q^2 = 1$$

where p and q are allele frequencies in a two-allele system, and p^2, $2pq$ and q^2 represent the expected frequencies of the A_1A_1, A_1A_2, and A_2A_2 genotypes respectively. Deviations from the expected Hardy–Weinberg proportions of genotypes could indicate the action of selection or inbreeding.

At equilibrium, the amount of variation in a population depends on two factors: the effective population size (N_e) and the mutation rate (μ). This is typically summarized using the parameter θ:

$$\theta = 4N_e\mu$$

Estimates of θ can be derived from various measures of diversity including heterozygosity, nucleotide diversity, and gene diversity. Average heterozygosity is simply the number of heterozygous individuals (having two different alleles at a locus) divided by the total number of individuals. In Hardy–Weinberg equilibrium, the expected number of heterozygotes for a locus with two alleles is $2pq$ (see above). When there are more than two alleles (as is typically the case), we can calculate homozygosity (having the same two alleles at a locus) by summing the squared frequency for each allele, and subtract this total from 1 to derive expected heterozygosity (since 1 minus the homozygosity equals heterozygosity). Nucleotide diversity is a measure of the mean sequence divergence among alleles, while gene diversity is a measure of the number of different alleles in a population.

A common way to compare the level of diversity among and within populations is by using the inbreeding coefficients proposed by Sewall Wright in 1969, called *F-statistics*. The inbreeding coefficient can be defined as the probability that a pair of alleles in an inbred individual is identical by descent. Within a population, we can define F_{IS} as a measure of the reduction in heterozygosity (H) in an individual due to nonrandom mating ($F_{IS} = (H_S - H_I)/H_S$), where H_S is the expected heterozygosity for the population (based on Hardy – Weinberg expectations) and H_I is the average heterozygosity of all genes in an individual. We can use the same reasoning to assess genetic structure among populations. In this case, $F_{ST} = (H_T - H_S)/H_T$, where H_T is the expected heterozygosity for the entire sample (all populations combined) and H_S is the average H_S among all individual populations. It is essentially a measure of the proportion of genetic variance that is explained by differences among as opposed to within populations, and it varies over a range from 0 (no differentiation among populations) to 1 (completely isolated populations).

The application of these and similar methods allow estimates of gene flow, the time since populations diverged, the relative effective size among populations, and variation in mutation rates for a given gene among populations. The application of statistical methods such as Bayesian inference and autocorrelation can also help interpret patterns of population structure and mixing, though further detail is beyond the scope of this review. Additional

methods based on likelihood estimates and measures of genetic similarity can assign individuals to populations on the basis of their genotype (typically using microsatellite DNA loci) and can assess the dispersal behavior of different classes of individuals (e.g. males vs females).

Another important method reflects the way in which we think about the relationship among genotypes. Through phylogenetic reconstructions, we can explore possible historical relationships among taxa, and this has been very useful at the population level (often referred to as *phylogeography*). It also allows us to think about the ancestral relationship between pairs of genotypes. If we think backwards in time, we can consider the time when two evolutionary paths come together, at the point of coalescence. This represents the point at which these genes shared a most recent common ancestor and the time that has elapsed since then (the coalescence time). The pattern of coalescence is affected by the processes of demographic change and natural selection, and therefore allows inference about these processes. The utility of this approach is greatly facilitated by DNA-sequencing nonrecombining genomes (such as mitochondrial DNA), which allows us to trace lineages through the comparison of variation among homologous sequences at the level of the nucleotide.

7 Conclusions

Molecular methods have made it possible to test theoretical expectations about genetic diversity directly and have greatly facilitated our understanding of populations at the genetic level. Every year, there are significant advances that make this work ever more powerful and more routine. This has especially included advances in the computer-based screening of gels for DNA sequences and genotypes, and the software developed to analyze such data. There have also been exciting advances in the methods of interpretation, some of which are described above. In future, technology that allows us to further increase the number of sequences we analyze and the number of genotypes we can screen will allow greater insight into the evolution of population structure and diversity. These data allow us to understand evolutionary processes at a fundamental level and help us protect diversity in natural populations and thereby species for future generations.

Keywords

Heme
Protoporphyrin IX, the ring molecule holding an iron atom to which oxygen can bind.

Distal
The side or face of a heme molecule within Hb, which is free to bind oxygen.

Proximal
The side or face of the heme that is covalently linked to a histidine side chain.

Allostery
The phenomenon of a protein changing shape on binding ligands or substrates.

Cooperativity
The phenomenon of multiple ligand binding showing an increase (positive cooperativity) or decrease (negative cooperativity) in ligand affinity with increasing ligation.

P_{50}
The partial pressure of oxygen, usually measured in mmHg, needed to half-saturate a sample of Hb.

Hemoglobin is the oxygen-carrying protein of the blood, binding oxygen at iron-containing heme groups within the protein. Its structure is well characterized in both the deoxy and oxy forms, and comparison of these structures has shown how the protein changes its conformation as the number of bound oxygen molecules increases. These conformations have different ligand affinities, and so the protein can regulate how tightly oxygen is bound. A detailed understanding of the protein mechanism and control of ligand affinity requires the study of mutant proteins. Many mutated hemoglobins have been detected clinically, but these naturally occurring mutants have generally been of limited use in analyzing hemoglobin function. A number of expression systems have therefore been devised to produce human hemoglobin from microorganisms. These systems make possible the alteration of

specific residues or groups of residues so that their functional role may be tested. Together with the wide variety of biophysical techniques employed in the study of hemoglobin, genetic engineering has proved to be a powerful tool for testing the function of different parts of the protein. Hemoglobin remains one of the most important systems for testing ideas concerning protein folding and function, protein interactions, and cooperativity. It is far from being completely understood, despite the widespread impression that this is so. The last decade has seen an explosion in hemoglobin research triggered by the ability to create artificial mutants of hemoglobin, and the increasing need for a safe, cheap blood substitute. This review attempts to highlight some of the advances made in recent years.

1 Introduction

Myoglobin (Mb) and hemoglobin (Hb) were the first proteins whose structures were determined by X-ray crystallography, the analysis of X-rays scattered from the protein in crystalline form. Both Mb and Hb form highly ordered crystals, which allow fine details of the protein to be resolved. Human carbonmonoxy hemoglobin has now been refined to 1.25-Å resolution (Protein Data Bank entry 1IRD (see the Protein Data Bank home page http://www.rcsb.org/pdb/)). Mb is an oxygen storage protein of the muscle. It consists of a polypeptide chain wrapped around a heme group, a ring molecule with an iron atom at its center, which gives the molecule its red color (Fig. 1). The polypeptide is coiled into eight α-helices (labeled alphabetically from the N-terminus) packed together to give a compact, roughly spherical shape. The heme is buried in a cleft in the protein between the E- and F-helices, and the iron atom is covalently attached to a histidine residue on the F-helix. Since this is the eighth residue from the N-terminus of the helix, it is known as *residue F8* as shown in Fig. 2. Oxygen binds to the opposite side of the heme, the ''distal'' side, in a ligand pocket. Two amino acid residues, histidine E7 and valine E11, touch the ligand in oxy-Mb. Both these residues are highly conserved throughout globin evolution. Histidine E7 is called the *distal histidine* to distinguish it from the ''proximal histidine'' F8. Mb binds to oxygen in a simple fashion with a single, fixed equilibrium constant.

As the oxygen-carrying protein of the blood, Hb has the conflicting task of

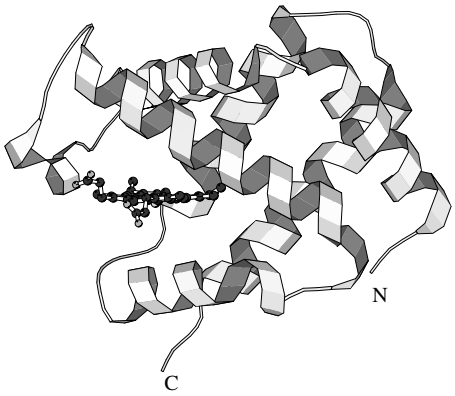

Fig. 1 A schematic diagram showing the highly helical tertiary structure of α globin. The polypeptide is shown as a ribbon trace of the Cα atoms, and the heme molecule is shown as individual atoms.

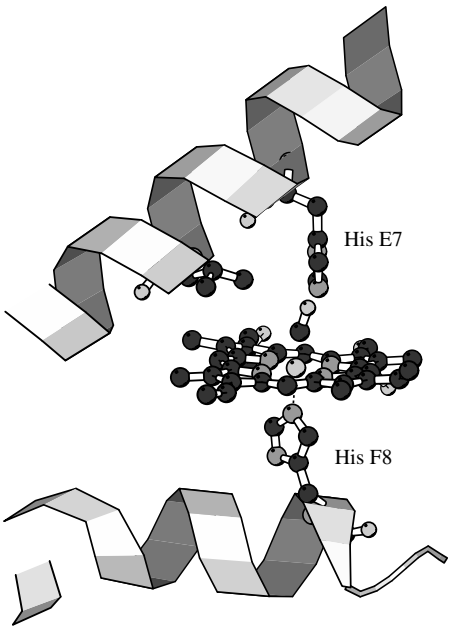

Fig. 2 A closer view of the heme region of β-globin, showing carbon monoxide bound to the heme iron. The heme is sandwiched between the E- and F-helices, and is covalently attached to the F-helix through the side chain of the histidine F8 residue. The E7 residue is also a histidine, which contacts ligands bound to the distal side of the heme.

binding oxygen tightly in the lungs and releasing it readily in the tissues. A simple oxygen-binding protein such as Mb would be extremely inefficient at transporting oxygen in this way. Hb changes its oxygen affinity with oxygen partial pressure, lowering it sufficiently to release oxygen around the body at relatively high oxygen concentrations. The means by which this is accomplished remained a puzzle until the structure was solved in both liganded and unliganded forms by Perutz and coworkers. The molecule consists of four Mb-like subunits, two α-type and two β-type, each containing a heme group. The four subunits form two $\alpha\beta$ dimers, which adopt slightly different positions relative to each other in the liganded and unliganded forms. Each $\alpha\beta$ dimer is relatively rigid. In the deoxy form, the protein constrains the iron atom at the center of each heme group, pulling it toward the proximal side. This form, which has more bonding interactions between the $\alpha\beta$ dimers than the oxy form and is energetically favored in the absence of ligand, is known as the *T-(tense)state*. Ligand binding at any heme serves to weaken the dimer–dimer interaction, and as more ligands bind to the protein, it favors the R-(relaxed)conformation more. In this form, the subunits have a higher oxygen affinity because the constraints on the movement of the iron atom are no longer there. Several allosteric effectors are known, which shift the equilibrium toward the T-state. These include chloride ions, hydrogen ions (above pH 6) and organic phosphates. Human red cells contain 2,3 diphosphoglycerate (DPG), which lowers the oxygen affinity of Hb substantially. Inositol hexaphosphate (IHP) is a nonphysiological ligand, which exerts an even stronger effect.

Researchers in the hemoglobin field are often asked why they work on a protein that is ''solved.'' This is a natural question; it is now more than 30 years since Perutz put forward his famous ''trigger'' hypothesis that oxygen binding to the heme iron atoms pulls on the proximal histidine, breaking salt bridges holding the tetramer in the T-conformation and allowing the protein to relax to the R-state. In the Perutz model, the protein makes a concerted switch between two possible quaternary states. This idea has been subjected to numerous tests and is found to be in very good agreement with the experimental data. It is the classic example

of protein allostery found in biochemistry textbooks, and is unquestioningly accepted by generations of undergraduates. It cannot, however, be the whole truth since the intermediates on the pathway between the T- and R-states cannot have infinite energy (though at least one paper has suggested they might). The nature of these intermediates, and their energy relative to the deoxy T- and oxy R-states, has been a topic of heated debate for decades and is not yet fully resolved. The genetic engineering of hemoglobin opened up an enormous array of possible experiments through which the limits of the Perutz model could be tested and our understanding of hemoglobin expanded.

It should also be realized that the data with which Perutz worked 30 years ago were of a different standard when compared to X-ray data collected today. X-ray generators were very weak, and the film used to detect scattered X rays was not sensitive enough for accurate measurements of weak reflections. Today's synchrotron X-ray sources are many orders of magnitude brighter than simple laboratory generators, and image plate and CCD detectors allow the very rapid acquisition of accurate data to high resolution from small protein crystals. As crystallographic hardware and software have improved, it has become possible to refine Hb structures to higher resolution, even allowing individual atoms to be visualized in the best cases. The best current refinement of oxyHb was performed in 1983. Although at a nominal resolution of 2.1 Å, the geometry and temperature factors of the model clearly show that the data and software quality that existed 20 years ago were much inferior to those of today. Crystallographic laymen should not be fooled into thinking that the resolution or the crystal ''R-factor'' are uniformly reliable indices of model quality. Since the methods of data collection and refinement can also affect the final model, it is not too surprising to find that crystal structures of different Hbs solved by the same research group at the same time are more similar in some ways than models of native Hb from different groups.

Furthermore, it should be emphasized that crystallographic structures of even the highest quality cannot answer all questions concerning Hb binding to oxygen. Crystallography can tell us where atoms are, but not necessarily what they do, or how much energy is stored in a particular atomic interaction. In order to understand the relationship between the protein structure and its function, it is necessary to measure the affinity and kinetics of Hb for particular ligands, under different conditions. For example, it was noticed that the positions of the distal histidine and valine side chains are different in the α- and β-subunits, and appeared to have different functional roles. This observation provided the stimulus for the engineering of mutant proteins, but without the functional experiments the crystallographic hypotheses cannot be tested. Even when only clinically detected mutant Hbs were available, several of these played an important role in helping Perutz formulate his ideas. The ability to produce any desired mutant on demand allows us to investigate aspects of Hb function that are still incompletely understood, such as the Bohr effect, the change in oxygen affinity with pH. Functional analysis of such mutants complements the crystallographic work and provides a deeper insight into the protein mechanism. More recently, the production of Hb in microorganisms has allowed the protein to be labeled isotopically, greatly increasing the usefulness of nuclear magnetic resonance (NMR) in addressing structural and functional issues of such

a large protein. This review focuses on the genetic engineering of hemoglobin; metal-substituted hemoglobins, chemically modified Hbs, and native animal Hbs fall outside its scope. The reader should remember, however, that our understanding of this protein has come from a wide range of biophysical techniques applied over many years. Indeed, hemoglobin has been a principal protein used to hone many of those techniques, now widely applied elsewhere.

2 Expression Systems

The first requirement for a high yield of the protein of interest is a strong promoter that directs the transcription of the gene to form messenger RNA (mRNA). The promoters used are generally inducible. The first system successfully used to produce usable quantities of human globins in a microorganism utilized an *Escherichia coli* plasmid carrying the λ P_L promoter, which is switched off with λ-repressor. At that time, in the mid 1980s, this was the expression system of choice; a temperature-sensitive mutant of the λ-repressor was used to prevent transcription in the early growth phase. Gene expression was switched on by heat-shock at 42 °C to inactivate the repressor. The synthesis of large amounts of protein also depends on efficient translation of the mRNA. The expression of eukaryotic genes in *E. coli* is often difficult due to differences in codon usage and the mechanism of translation initiation. In *E. coli*, ribosome binding to mRNA involves base pairing of the 16S rRNA (part of the 30S subunit) to the Shine–Dalgarno region, about nine bases upstream of the initiator AUG codon. Secondary structure of the mRNA around the initiation site can have a marked inhibitory effect on translation. Indeed, if such a secondary structure is present, it may be removed only by altering the codons corresponding to the N-terminus of the protein to be expressed. Many eukaryotic genes, α- and β-globin among them, are very poorly expressed by simple expression systems. To overcome this problem, Nagai and Thøgersen developed the cleavable fusion protein expression vector using the blood clotting factor FXa. A leader sequence from a highly expressed protein is coupled to a short sequence encoding the tetrapeptide recognition site of FXa (Ile-Glu-Gly-Arg) and then the coding sequence of interest. The fusion protein produced in high yield can then be treated with FXa to release the C-terminal region corresponding to the desired polypeptide product. This method is now used routinely with histidine-tagged proteins, but β-globin was one of the first proteins to be expressed as a cleavable fusion protein. α-globin proved more difficult to express with this system, possibly due to the structure of the mRNA around the initiation codon. A key advantage of this system is that it produces mammalian globins with the correct N-terminal amino acids, with the initiator methionine removed. *Escherichia coli* is relatively inefficient at removing this residue if the second residue is valine or serine, and the extra methionine can have a marked effect on the functional properties of the protein. The main drawback, however, is that the fusion protein method produced inclusion bodies in *E. coli*, and requires the globin to be dissolved in urea or guanidine hydrochloride before cutting with FXa and refolding with heme. Overall, the cleavage/refolding procedure has an efficiency of about 25% in general, but can be lower if unstable mutants are made, so considerable effort is required to make

these mutants on the 50 to 100 mg scale. The method is, however, capable of synthesizing Hb, which is structurally and functionally identical to native human Hb. The report by Nagai, Poyart, and Perutz on the oxygen-binding properties of this protein is the first paper demonstrating the production of functional Hb using a bacterial host.

A completely different expression vector, described by Hoffman and colleagues in 1990, contains coding sequences for both α- and β-globin in a single operon, the two being linked by a ''translational coupler.'' Ribosomes produce both types of globin from a single mRNA. Coexpression of α- and β-globin in this way within the cell results in the production of folded, fully functional tetrameric Hb. *Escherichia coli* increases production of heme to such an extent that the cells turn red. The globin genes were constructed from synthetic oligonucleotides to optimize codon usage, and transcription is driven by an IPTG (isopropylthiogalactoside) inducible promoter. Interestingly, the expression of β-globin alone gave mainly insoluble protein with no heme incorporated, so the coexpression of α- and β-globin appears to be necessary for the protein to fold. Hb produced in this way shows 4 hemes per tetramer and less than 5% oxidation of the hemes. The visible spectrum is identical to that of native HbA. However, amino acid sequencing shows that the β-subunits, and 90% of the α-subunits, retain the initiator methionine. Although the oxygen affinity and cooperativity of the protein are very close to those of native HbA, the Bohr effect is roughly 50% less, reflecting the role of the N-termini in mediating the proton dependence of the oxygen affinity. The binding of inositol hexaphosphate (IHP) to the protein also appears to be weakened by the extra methionine residues.

Hernan and colleagues investigated the importance of optimizing the codon usage in the expression of α- and β-genes in *E. coli*. Using a T7 expression system, they reported the first successful attempt to express β-globin from its cDNA as a nonfusion protein. In common with Hoffman et al., these researchers found that expression of β-globin alone led to the production of large amounts of insoluble protein within the cell. Attempts to express α-globin alone were unsuccessful, indicating that either the mRNA or the protein is less stable than its β-globin counterpart. The expression of β-globin to a high level (as an inclusion body) allowed the protein to be refolded with native α-globin using the procedure developed by Nagai, but without FXa cleavage. Amino acid sequencing showed retention by the recombinant protein of the deformylated N-terminal methionine residue. This system, therefore, produces Hb tetramers identical to HbA except that the β-subunits have an extra N-terminal residue.

Clearly, the principal problem in synthesizing Hb in *E. coli* is the inefficient removal of the N-terminal methionine from the protein. Two approaches have been used to overcome this difficulty. Firstly, Wagenbach and colleagues used the yeast *Saccharomyces cerevisiae* as the host organism. Coexpressing α- and β-globin genes in yeast yielded folded, tetrameric Hb with correctly processed N-termini, showing the different preferences of eukaryotic and prokaryotic methionyl aminopeptidases. Ho and colleagues used a different approach and chose to overexpress the native methionyl aminopeptidase together with globin genes. This method also produces authentic human Hb. The pHE2 plasmid made by the Ho group is now the most widely used expression system, and has led

to an enormous increase in the number of publications on artificial Hb mutants. Any system in which the host microorganism yields folded tetrameric Hb with heme incorporated is significantly easier to work with than the original Nagai system. Concerns have been raised, however, regarding the folded Hb produced in *E. coli*, which is reported by some authors to be slightly more prone to oxidation than HbA. Refolding the chains from denaturant produces protein with spectral and functional characteristics essentially identical to those of native HbA, but such systems cannot be used to make protein on a large scale without considerable effort.

Although strictly outside the scope of this review, there is also a considerable body of research on recombinant Mb. This is largely based on work from the Sligar group, which succeeded in producing folded, functional Mb within *E. coli*. With greater difficulty, the FXa fusion method can also be used to make mutant Mbs. Mb has served as a very useful model system, especially in testing ideas concerning the heme pocket. Since it is much simpler than Hb, having only a single subunit, it is rather easier to work with. Functional and crystallographic analyses of mutant Mbs, however, have played an important role in shaping ideas concerning ligand binding and selectivity of Hb.

3 Distal Residues

Two very highly conserved residues in the distal pocket lie in van der Waals contact with ligand molecules, a histidine (E7) and a valine (E11). In deoxy Hb, the distal valine of the β-subunit lies over the heme and obstructs oxygen binding. The equivalent residue in the α-subunit is further from the iron, and oxygen can seemingly be accommodated more readily. It was therefore predicted that ligands will bind to the α-subunits first. Kinetic experiments have clearly shown, however, that the very bulky *t*-butyl isocyanide binds to the β-subunits faster than the α-subunits, a result that underlines the difficulties in predicting function from structure. Further differences in the distal residues were seen in the high-resolution structure of oxy-Hb. In the α-subunits, a hydrogen bond was found between the oxygen ligand and the distal histidine. Since hydrogen atoms are very weak X-ray scatterers, hydrogen bonding in X-ray crystallographic models of proteins is generally inferred from the positions of other atoms. A similar hydrogen bond has been found in oxy-Mb, and demonstrated by neutron scattering. Strangely, no such hydrogen bond appeared to form in the β-subunit.

The interactions between the distal residues and bound ligands, proposed on the basis of crystallographic structures, could be tested only by obtaining suitable mutant Hbs in which the distal residues of the α- and β- subunits were replaced with other amino acids. To examine the proposed steric hindrance of the valine E11 residue, a number of different mutants are needed in which this amino acid is replaced with larger or smaller apolar residues. If the distal valine side chain does sterically hinder oxygen binding, these mutations should cause the oxygen affinity to change. Similarly, replacing the distal histidine residue with apolar residues will exclude the possibility of a hydrogen bond between the E7 residue and bound oxygen. If this bond were to occur in the native protein, the oxygen affinity should fall.

Aspartate, glutamate, and alanine have all been found at the E11β position in

naturally occurring Hbs. The first two of these mutants are unstable, since the introduction of a negative charge into the heme pocket greatly increases the rate of oxidation of the heme. Hb Sydney, $\alpha_2\beta$(E11 Ala)$_2$, is thermally unstable because the weakened heme–protein contact allows the heme to dissociate from the protein more easily. This mutant is potentially very interesting since the amino acid change is quite conservative. However, patients producing Hb Sydney also produce HbA, since humans carry two copies of the β-globin gene, and Hb Sydney cannot be separated from HbA since the two show identical electrophoretic behavior. Nevertheless, mixtures of Hb Sydney and HbA purified from hemolysate were shown to have increased oxygen affinity in the T-state. This experiment was one of the first in which it was shown that even conservative mutations can have important functional effects if they occur at key residues in the protein. To determine the behavior of the mutant more precisely, however, requires the synthesis of an artificial mutant.

3.1 Oxygen Equilibrium Curves

Since the principal function of Hb is to transport oxygen around the body, the majority of mutational studies of Hb have focused on the effects of amino replacements on the oxygen affinity of the protein. These measurements are carried out using an oxygen cell, ideally measuring spectral changes for both the oxygenation and deoxygenation curves to ensure that these are identical. These experiments show the well-known sigmoidal curves due to the increase in oxygen affinity with increasing oxygenation. The oxygenation was first studied in detail by Hill, who used a logarithmic plot (now named after him) to chart the oxygenation of the protein with increasing oxygen partial pressure. The slope of the curve is known as n, the cooperativity – the degree to which the ligation state of the hemes influences the ligand affinity of its neighbors. n_{max} is a very sensitive test of the quality of a sample of HbA. An important test for any expression system, therefore, is its ability to produce wild-type HbA with essentially identical oxygenation properties to those of HbA.

The Nagai and Thøgersen FXa fusion protein expression system led to the production of a number of mutant Hbs with altered distal residues in the β-subunit. Valine E11 was changed to alanine, leucine, and isoleucine, and histidine E7 was changed to glutamine. Upon comparison of the oxygen equilibrium curves of HbA and Hb (Val E11$\beta\rightarrow$Ala), it was found that the T-state oxygen affinity of the mutant protein is higher, but the R-state affinity is unaltered. Thus, the distal valine side chain does sterically hinder ligand binding, as suggested by the crystal structure, but only in the T-state. By determining the structure of deoxy Hb held in the R-state by a chemical cross-link, it has been shown that the β-chain distal valine moves only 0.3 Å from its position in T-state deoxy Hb, but it moves a further 0.7 Å in oxy-R state Hb. It seems that the smaller movement associated with the change of quaternary structure imposes greater strain on the ligand than the larger movement associated with ligation of the R-state.

The oxygen equilibrium curve of Hb Val E11$\beta\rightarrow$Leu is superimposable over that of HbA, the increase in size of the E11 residue having no effect on the oxygen affinity in either quaternary state. Hb (Val E11$\beta\rightarrow$Ile), however, shows a markedly reduced oxygen affinity throughout its

oxygen equilibrium curve but retains its cooperativity. The different properties of these proteins appear to be related to the flexibility of the E11 residue as much as to its size. Both valine and isoleucine are forked at the Cβ atom, which prevents rotation about the Cα–Cβ bond when these residues sit within an α-helix. In the crystal structure of Hb (Val E11$\beta\rightarrow$Ile), the δ-methyl group of the isoleucine E11 sits over the heme iron atom, pushing histidine E7 away and repelling ligands. Leucine E11 does not cover the ligand binding site or press against the distal histidine. It was clearly demonstrated that nonbonded interactions with the distal valine could reduce ligand affinity, and that the size and conformation of the E11β residue are important determinants of its ability to hinder ligand binding. Three α-chain distal valine mutants (valine $\rightarrow$ alanine, leucine, and isoleucine) have been made with a modified form of the Nagai and Thøgersen system. Their oxygen equilibrium curves are superimposable on that of HbA. The contrast in behavior between the two subunit types is exactly that predicted from the crystallographic structure of native HbA; the E11 side chain of the α-chain clearly exerts no direct control over the oxygen affinity in the way the equivalent β-globin residue does.

In deoxy Hb, a water molecule is found within the heme pocket of the α-subunits but not the β-subunits. This water is hydrogen bonded to the distal histidine and lies close to the position the second oxygen atom occupies in oxy-HbA. It was not clear from the structural data, however, whether this water molecule reduces the affinity for heme ligands by competing with them for occupancy of the heme pocket. The structures alone suggested no significant functional role for the water molecule, but a different conclusion was reached from the association rates of a number of ligands binding to mutant Mbs – the distal histidine slows down the rate of ligand binding by holding a water molecule in the heme pocket with a hydrogen bond. The role of this water molecule was further complicated by the finding that in cryo-cooled crystals of deoxy human Hb, one α-subunit has the water molecule while the other does not.

Hbs having the distal histidine of either the α- or β-subunits replaced by glycine were too unstable to permit the accurate measurement of the oxygen equilibrium curves, the heme rapidly oxidizing to the ferric state. The histidine was also replaced by glutamine, an α-apolar amino acid capable of donating hydrogen bonds. This mutation is found in the α-subunits of opossum Hb, but all other vertebrate Hb sequences determined have histidine at the E7 position. In the case of the β-subunit mutant, the replacement led to a rise in the T-state oxygen affinity of the protein, but the R-state affinity was unchanged. The electron density map of this mutant in the deoxy form showed the E7 glutamine residue to be well localized, but the Nε and Oε atoms of the side chain could not be distinguished. The higher T-state oxygen affinity was attributed to the relief of steric hindrance due to the greater flexibility of the glutamine compared to histidine.

3.2 Rates of Ligand Binding

More detailed information regarding the function of the distal residues has been obtained from the kinetic studies of ligand binding in which the R-state rate parameters of the mutant Hbs binding to oxygen and carbon monoxide were determined. The group of Prof. J.S. Olson in Houston, in particular, has studied the functional

effects of mutations in Mb and Hb in great detail. For Hb, the largest effects were found when histidine E7α was replaced by glycine. Although oxygen equilibrium experiments could not be carried out on this unstable mutant, it was possible to measure the association and dissociation constants of oxygen binding to R-state protein and to calculate the oxygen affinity ($K = k_{on}/k_{off}$). In native globins, the distal histidine residue blocks ligand access to the heme from the solvent, and must swing away from the heme pocket to allow ligands to enter or leave. Removing the imidazole side chain creates a channel to the heme iron so that diatomic ligands can enter the heme pocket unhindered. In α-globin, this change allows both CO and oxygen to bind to the protein about seven times faster. The dissociation rate of CO is not greatly affected, but the dissociation of oxygen increased 60-fold. Replacing histidine E7α by glutamine gave similar but smaller effects, and the oxygen affinity is considerably decreased by either mutation. When the native protein is compared with Hb (His E7$\alpha \rightarrow$ Gly), the distal histidine appears to stabilize bound oxygen by about 1 kcal mol^{-1} and to destabilize bound CO by about the same amount.

The β-subunits of Hb showed quite different functional behavior when the distal histidine residue was changed to other amino acids. Mutating histidine E7β to glycine, glutamine, or phenylalanine has remarkably little effect on the rates of oxygen or carbon monoxide binding. Each of the mutant β-subunits binds to these ligands with rates indistinguishable from those of the native subunit, despite the considerable differences in the nature of the E7 residues. Histidine E7β is not, therefore, an effective barrier to ligand binding, unlike its counterpart in the α-subunits, which is consistent with the relatively high association rates observed for the native protein. The dissociation rates are also insensitive to changes in the E7 side chain. This agrees with the 1983 crystallographic structure of oxy-Hb, which shows histidine E7β to be too far away and in an unsuitable position to form a strong hydrogen bond with bound oxygen. Replacing the distal histidine of Mb with phenylalanine reduces the oxygen affinity 130-fold, yet the same mutation has no effect on the R-state oxygen affinity of β-globin. Nevertheless, NMR results from the Ho group suggest the distal histidine of both subunits in HbA can hydrogen bond to oxygen in the binding site.

From the oxygen equilibrium curves, it is clear that replacing the α-subunit distal valine with other aliphatic apolar residues has no effect on the oxygen affinity. When valine is changed to leucine or isoleucine, the R-state oxygen association and dissociation rates remain the same, but mutating the E11 residue to alanine causes both rates to increase roughly sevenfold. This mutation also increases the association rate of carbon monoxide 10-fold, but does not alter the dissociation rate. These increases in association rates show that Val E11α must be a kinetic barrier to diatomic ligands binding. α globin (Val E11$\alpha \rightarrow$ leucine) shows CO rate parameters indistinguishable from those of the native protein; α globin (Val E11$\alpha \rightarrow$ leucine) seems to bind CO only half as quickly, but the rate is the same as that of the native protein within error. The kinetics of oxygen and CO binding to β-globin are unaffected by mutating the distal valine residue to either alanine or leucine. This finding agrees with the oxygen equilibrium curves, which show that these mutations leave the R-state oxygen affinity of Hb unchanged. Replacing valine E11β with isoleucine

lowers the oxygen association rate (and affinity) by about 10-fold. None of the β-globin E11 mutants showed an increase in association rate for either ligand.

3.3 Discrimination between Ligands

Carbon monoxide is constantly released into the blood by heme breakdown and binds to free heme very tightly. Hb, therefore, has to weaken the binding of carbon monoxide to remain able to transport oxygen. Oxygen binds to simple hemes in a bent fashion, whereas CO assumes a linear conformation perpendicular to the heme plane. There is no room for CO to bind in this way to heme proteins without severe steric strain, which led to the suggestion that heme proteins can discriminate between oxygen and carbon monoxide by selectively sterically hindering CO binding. This type of steric discrimination is found in some model heme compounds, so distal steric hindrance can lower CO affinity relative to oxygen affinity, but heme proteins do not necessarily behave in the same way. Native α- and β-globins have M values ($M = K_{CO}/K_{O_2}$) of about 250, while that of Mb is much lower, about 20. The M value of β-globin is little altered by replacing the distal histidine with glycine, but the same mutation in α-globin and Mb raises the M value to 7000 and 2000 respectively. Similarly, replacing valine E11 with alanine increases the M-value of α-globin to 2700 but does not affect the β-globin value significantly. The distal residues of both α-globin and Mb, therefore, discriminate against CO binding, both by selective steric hindrance and by the formation of a hydrogen bond with oxygen. The distal residues of β-globin do not behave this way, at least in R-state Hb.

The precise geometry adopted by CO in globins, and the energy penalty incurred by the steric clash with the E7 and E11 residues, have been the subject of numerous papers from crystallographic and spectroscopic groups. The discussion was occasionally marked by a distinct clash of these two cultures. The structure of carbonmonoxy Hb has in fact been refined several times, beginning with the 2.7-Å refinement by Baldwin (PDB code 2HCO). At this resolution, the heme geometry is rather imprecise and so in the model the heme was fixed as a rigid plane, and the ligand geometry cannot be modeled reliably. Higher resolution (2.1 Å) was achieved in 1991 by the Dodson group, who found the ligand in both subunits in a position almost perpendicular to the heme. This contrasted with an earlier model of Mb in which the ligand was modeled in a strongly bent conformation into rather ambiguous electron density, albeit at 1.5-Å resolution. A more recent HbCO model refined to 2.2 Å also shows a strongly bent ligand. Spectroscopic evidence has in general favored a linear Fe-C-O conformation. The best current model of HbCO in the Protein Data Bank is refined to 1.25-Å resolution, allowing individual atoms of the ligand to be visualized, and shows the ligand of both subunits lying close to the heme normal. MbCO has now been re-refined to even higher (1.15 Å) resolution (PDB code 1BZR), showing the ligand position to be similar to that in HbCO. Earlier crystallographic models of carbonmonoxyheme proteins may have suffered from ligand loss or heterogeneity, and problems with insufficient care in handling model restraints during refinement.

Resonance Raman spectroscopy is ideally suited to studies of heme proteins

since the well-characterized ligand bending and stretching frequencies are sensitive to any distortion caused by the protein. Different vibrational frequencies have been assigned to the stretching modes ν(Fe-CO) and ν(C-O). For carbonmonoxy HbA, these are 507 and 1951 cm^{-1} respectively, compared to 495 cm^{-1} and 1954 cm^{-1} for a simple model heme compound. HbCO gives a sharp line at 507 cm^{-1}, showing that both subunits have very similar environments for the ligand. Replacing the distal valine of either subunit with alanine, leucine, or isoleucine, or replacing valine E11β with methionine, produces no effect on any of these vibrational modes; the spectra of these seven mutant Hbs were shown by Lin and coworkers to be identical to that of HbA. This result is quite surprising, since it was known that the CO affinity of the mutant proteins is altered. The drop in CO affinity cannot be due to strong tilting or bending of the ligand away from the heme normal since this would bring about significant changes in the Raman spectrum. The ligand geometry therefore appears to remain unaltered in the different mutants and the steric strain is taken up by the protein moiety, not the ligand.

4 Proximal Histidine Mutants

Site-directed mutagenesis also permitted an ingenious test of Perutz's stereochemical model by deleting the bond between the proximal histidines and the heme iron atoms in the α- or β-subunits, or both together. Barrick and colleagues of the Ho group showed that Hb mutants in which the proximal histidine is replaced by glycine can mimic HbA in the presence of imidazole, which binds to the proximal face of the heme just like a histidine side chain. Removing the covalent link between the heme and the F-helix releases any tension between the two. These experiments showed clearly that the proximal as well as the distal histidines behave differently in the α- and β-subunits, confirming the earlier results of Fujii and colleagues of the Morimoto group, who worked extensively with metal hybrid Hbs. The rate of carbon monoxide binding was found to be controlled by proximal effects in the α-subunits rather than the distal effects, which are much more pronounced in the β-subunits. Proximal detachment significantly increased the ligand affinity and reduced cooperativity. It was found that, in the presence of CO bound to all four hemes, releasing tension in the α-subunits led to considerable T-structure, but releasing tension in the β-chains did not. Releasing tension in both led to an intermediate between the two. Barrick and colleagues showed that detachment of the α- and β-hemes has opposing effects, but their results can be interpreted as showing that the position of the β-heme iron is relatively insensitive to the quaternary state, and that distal effects are more important in this subunit. rHbCO (His87α→Gly) is held in the T-state by the α-chain freed of the pull of the heme iron; the additional mutation in rHbCO (His 87α→Gly/His92β→Gly) allows the β-heme to move more in response to distal ligand, leading to a smaller value of L, the allosteric equilibrium constant, [T]/[R]. rHbCO (His 92β→Gly) is fully in R-state since the α- subunit iron is pulled close to the heme, and the ligated heme in the β-subunit is freer to move away from Val E11. This mutant also showed a tendency to split into $\alpha\beta$ dimers. Although, the loss of heme-F helix coupling prevents quaternary structure switching, in accordance with the

Perutz model, residual cooperativity was found indicating additional heme–heme communication pathways that do not involve the Fe–His bond.

5 C7 Mutants

Of all the hydrogen bonds and salt bridges in the $\alpha_1\beta_2$ interface of deoxy Hb, the hydrogen bond between tyrosine C7(42)α_1 and asparagine G1(99)β_2 appears to be one of the strongest. Asp 99β is altered in several clinically detected Hbs that have high oxygen affinity and bind oxygen noncooperatively as a result of the destabilization of the T-state. Tyr42α has not been found to be altered in a naturally occurring mutant, however. This residue has been mutated to phenylalanine and histidine using the Nagai and Thøgersen system. Hb Tyr42(C7)$\alpha\rightarrow$Phe shows properties very similar to those of the natural Asp99β mutants, indicating that the altered oxygen binding by these proteins results from the loss of the hydrogen bond rather than from a change in the size or shape of the residues. Replacing C7α with histidine gives a protein with properties intermediate between HbA and Hb Tyr42(C7)$\alpha\rightarrow$Phe, showing that a weak hydrogen bond can form between the histidine and the asparagine, thus allowing the protein to bind oxygen cooperatively.

The β-subunit residue equivalent to tyrosine 42α is phenylalanine 41β. This has been mutated to tyrosine, in an attempt to see if the newly introduced hydroxyl group can hydrogen bond to Asp94α, stabilizing the T-state. This mutation has been discovered clinically (Hb Mequon), but its properties were studied only as a hemolysate. The R- and T-state oxygen affinities of the purified protein were similar to those of HbA. L_0, the allosteric equilibrium constant of deoxy Hb, was higher for the mutant protein, so the T-state is stabilized. The binding of chloride and 2,3 diphosphoglycerate (DPG) were normal. Molecular dynamics simulations have shown that the tyrosine residue is not in fact likely to interact with Asp94α; probably it hydrogen bonds to the carbonyl group of His97(FG4)β in the same β-chain. It is proposed that this interaction stabilizes the hydrogen bond between Asp99β and Tyr42α.

6 N-terminal Mutants

As described earlier, the synthesis of human α- and β-globin in *E. coli* as nonfusion products results in proteins carrying an extra methionine residue at the N-terminus. Three such proteins have been synthesized and described in detail, one carrying the extra residue on the β-chains (''$\beta + 1$Met''), and the mutants Val1(NA1)$\beta\rightarrow$Ala and Val1(NA1)$\rightarrow$Met. The last of these was made by simply deleting the first valine codon so that the methionine replaces valine1β. Changing the first codon to alanine allows *E. coli* to remove the initiator methionine. The β-chains were refolded with heme and α-globin after purification. These mutants show similar oxygen binding and identical CO binding kinetics to HbA in the absence of allosteric effectors. In the presence of IHP, the CO binding of $\beta + 1$Met is significantly altered, but the other mutants behave normally. None of the mutations appeared greatly to alter the dimer–tetramer equilibrium or cooperativity, though the mutants all showed lower oxygen affinity than HbA. The allosteric effects of DPG was abolished and the effect of IHP diminished in the case

of Hb $\beta + 1$Met. The Val1(NA1)$\beta \rightarrow$Met mutant was found to have a Bohr effect identical (within error) to that of HbA.

The crystal structures of the three mutants have been solved in the deoxy form and refined to 1.8-Å resolution to observe the perturbations caused by the changes. In deoxy HbA, valine 1β makes several contacts with the H-helix and EF corner of the same β-subunit. The hydrophobic side chain lies in a pocket between these two, and the α-amino group forms a hydrogen bond with the carbonyl oxygen atom of leucine 78β. An anion-binding site found between valine 1β and lysine 82(EF6)β binds phosphate and sulfate ions, but since the crystals were grown from ammonium sulfate, the ion is sulfate in this case.

In all three mutants, the structural changes are localized to the N-terminus of the β-subunits, but the $\beta + 1$Met and Val1$\beta \rightarrow$Ala mutants showed different changes from the Val1$\beta \rightarrow$Met. In the first two, the amino-terminus of the β-chain becomes more mobile and the affinity for anions drops. Nearly all of the interactions with the H-helix and EF corner are weakened or broken as the N-terminus moves away. This effect is greater in the $\beta + 1$ Met mutant, the extra methionine nearly abolishing anion binding. In Hb Val1$\beta \rightarrow$Ala, the β-subunit N-terminus moves toward the EF corner so that the α-amino group can bind to Asp79(EF3)β. This group then competes with anions for the amino group and so lowers anion affinity. Unlike the other two mutants, Val1$\beta \rightarrow$Met increases the affinity for anions and decreases the mobility of the N-terminus. The X-ray crystallographic difference map between this mutant and HbA clearly shows extra density for the methionine and the bound sulfate. The main chain coordinate shifts are smaller in this mutant than in the other two, although the more bulky methionine side chain causes some movement away from the H-helix. This mutant therefore shows the least perturbed structure, yet has the greatest difference in oxygen binding affinity compared to HbA.

How can this apparent anomaly be explained? The most likely explanation comes from the study of Hbs from ruminants such as cows, which have lower intrinsic oxygen affinity than other mammalian Hbs. Perutz and Imai noted that these Hbs have large hydrophobic residues at the 2(NA2)β position and proposed that such proteins interact more tightly with the H-helix and EF corner, pulling the A-helix with them, stabilizing the T-state in a manner analogous to DPG binding to HbA. This mechanism fits very well with the observed functional and structural properties of the Val1(NA1)$\beta \rightarrow$Met mutant. Increased anion binding to the N-terminus of the β-chain in this mutant also agree with the observation that bovine Hb shows increased oxygen-linked chloride binding.

7
Trp37(C3)β

Both from the earliest crystal structures and, more clearly, from the later X-ray studies of T-state Hb with varying degrees of ligation by Paoli and coworkers, it is evident that Trp37β at the $\alpha_1\beta_1$ interface is a key residue in Hb function. Four mutant β-globins in which this Trp is replaced by Tyr, Ala, Gly, or Glu have been expressed in *E. coli* and reconstituted into tetramers with normal α-globin and subjected to a variety of analyses including crystal structure determination. Kinetic measurements of CO binding to

the deoxygenated mutant Hbs and analytical gel chromatography indicate that the tetrameric form is destabilized, resulting in considerable dissociation of even the deoxygenated hemoglobins into $\alpha\beta$ dimers at micromolar protein concentrations. Even with IHP added to stabilize the T-state, the normal behavior of HbA was not restored. The substitutions at 37β showed the same order of tetramer destabilization, increase in oxygen affinity, decrease in cooperativity and apparent tension in the iron–histidine bond: Tyr < Ala < Gly < Glu. Both tertiary and quaternary structure changes were found in the X-ray models of the deoxy mutant Hbs. The tertiary changes centered around Asp94(G1)α–Pro95(G2)α and Asp99(G1)β–Asn 102(G4)β, with no significant tertiary changes seen within the C-helix carrying the mutated residue. The mobility of the last two residues of the α-subunits showed increased mobility, and, in the Gly and Glu mutants the Fe-His(F8) bonds in the α- and β-subunits were found to be shortened. These results indicate that the globin fold is less able to restrain the deoxy heme iron from moving toward the heme plane if Trp37β is altered.

A more detailed study of Hb dimerization was reported by Vallone and colleagues, who measured the dissociation constant for five single and three double mutants of HbCO by analytical ultracentrifugation. The free energy change of dimerization was found to vary linearly with the hydrophobic surface area buried. Each square Ångstrom of hydrophobic surface area was found to increase the binding energy by 15 cal mol^{-1}, in good agreement with the theoretical estimate by Eisenberg and MacLachlan. Other mutagenic studies by the group of Manning suggest that residues distant from the contact interface may also contribute significantly to the free energy of dimer–dimer association.

8 Blood Substitutes

The need for an artificial blood substitute has been highlighted in recent years by concern regarding blood-transmitted diseases, but another considerable problem is the failure of the supply of donated blood to meet the rising demand. To be useful, the desired blood substitute must be nontoxic and long-lasting, and it must have oxygen-binding characteristics close to those of whole blood. Hb itself is an obvious starting material to make a suitable oxygen-carrying solution, but there are substantial problems associated with the introduction of free Hb into the circulation. First the plasma protein haptoglobin binds to Hb to form a complex, which is rapidly removed from the bloodstream. Once the haptoglobin level has dropped, free Hb passes through the kidneys as $\alpha\beta$ dimers. Free Hb is also liable to irreversible oxidation to metHb, which does not bind oxygen. In any case, blood has an oxygen affinity substantially lower than free human Hb because of the DPG present inside the red cell.

Since even highly purified Hb derived from human blood is harmful when introduced into the bloodstream, the protein must be modified in some way before it can be used as a blood substitute. A great deal of effort has been devoted to finding suitable chemical modifications to stabilize the tetramer and lower its oxygen affinity. However, any substitute based on human blood still retains some risk of transfer of pathogens from the donor, and the production of Hb on a large scale in microorganisms seems a more likely route to a safe product. As mentioned earlier, ruminant Hbs have an intrinsically low oxygen affinity in the absence of DPG and it has been suggested

that bovine Hb may be more suitable for modification into a blood substitute. The use of transgenic animals might also be used to produce human Hb (or a variant) in an animal host to prevent antigenic responses in patients, but there are still concerns regarding pathogens in Hb from such sources.

Three problems remain though: the short lifetime of free Hb in the blood, the need to reduce oxygen affinity while maintaining cooperativity, and the reactivity of Hb with nitric oxide, NO. The first difficulty, Hb dissociation into dimers small enough to pass through the kidneys, can be overcome by cross-linking the tetramer. An ingenious means of covalently linking two $\alpha\beta$ dimers without using chemical methods is described by Looker and coworkers. These investigators, noticing that the N-terminus of one α-chain is close to the C-terminus of the other, reasoned that a tandem fusion of two α-globin chains would be able to fold with β-globin and function as a normal tetramer, but would prevent dissociation into $\alpha\beta$ dimers. The expression vector produced is very similar to that of Hoffman et al. but contain two copies of the α-globin gene fused by a glycine codon instead of a normal α-globin gene. The "di-α-globin" gene and the β-globin gene are organized in a single operon. Upon induction with IPTG, host *E. coli* cells produce β-globin and the di-α-globin, which fold and incorporate heme to give a molecule very similar in overall structure to HbA. The fusion of the α-subunits was not expected to alter the oxygen affinity of the protein. Naturally occurring mutants described clinically were therefore examined to find the one with suitable properties, namely, low oxygen affinity and high stability. Looker et al. identified Hb Presbyterian (Asn 108$\beta \rightarrow$ Lys) as a suitable mutation.

Four mutant Hbs were synthesized:

rHb 0.0: (Val1$\alpha \rightarrow$ Met), (Val1$\beta \rightarrow$ Met)
rHb 0.1: di-α Hb (Val1$\alpha \rightarrow$ Met), (Val1$\beta \rightarrow$ Met)
rHb 1.0: (Val1$\alpha \rightarrow$ Met), (Val1$\beta \rightarrow$ Met, Asn108$\beta \rightarrow$ Lys)
rHb 1.1: di-α, (Val1$\alpha \rightarrow$ Met), (Val1$\beta \rightarrow$ Met, Asn 108$\beta \rightarrow$ Lys)

All four proteins showed substantially reduced Bohr effects and lowered cooperativity. However, rHb 1.1 shows oxygen affinity comparable to that of human blood. This protein was crystallized in the deoxy form to determine its structure. The Asn108$\beta \rightarrow$ Lys mutation causes substantial shifts of the B- and G-helices, but the mechanism by which it reduces oxygen affinity was not clear. The crystal structure was solved a few years later.

The linking of the α-subunits has been shown to increase the intravascular half-life of Hb three- to fourfold in rats, and kidney function was not detectably impaired in dogs when 30% of the blood volume was replaced with an isotonic solution of rHb 1.1. Clinical trials with rHb 1.1 and other cross-linked Hbs derived from human blood showed a marked hypertensive effect due to the reaction of the free Hb with nitric oxide. This unforeseen difficulty has in fact proved the major stumbling block for all attempts to produce a safe blood substitute from Hb, natural or artificial.

8.1 Nitric Oxide

Nitric oxide (NO) acts as a chemical messenger in the control of many important processes in the human body, and a vast literature has grown up around its effects, in a remarkably short space of time. NO

activates guanyl cyclase, leading to a variety of tissue-specific responses. NO is highly unstable and was therefore believed to act only locally. The introduction of free Hb into the circulation can remove NO by two main reactions – firstly, the direct binding of NO to deoxy hemes, and secondly, the oxidation of oxy-Hb by NO to give metHb and nitrate. NO can also bind to metHb and reduce it to the ferrous form, but this reaction is probably too slow to have any clinical relevance. The rate of the second reaction can be lowered significantly by increasing the bulk of apolar residues in the heme pocket. It has been shown that the reactivity of both α- and β-globin to NO can be reduced in this way. A series of recombinant Hbs has been produced with a range of rate constants for NO-induced oxidation, and it has been demonstrated that the hypertensive effect of these mutants in rats correlates very well with this reaction rate. In contrast, the overall oxygen affinity and autooxidation rates of the rHbs did not correlate with the observed changes in blood pressure. The data also suggest that the entire hypertensive effect may be attributed to the reaction of NO with deoxy and oxy-Hb.

This last point was somewhat contentious in the 1990s, following reports suggesting that Hb might have a previously unrecognized function as a NO transporter. It was proposed by Stamler and coworkers that the single cysteine residue in human Hb, 93β, could bind NO when the protein is oxygenated and in the R-state, and then release it as the protein switched back to the T-state on losing oxygen in the tissues. Injecting free Hb locked in the R-state should therefore cause a greater hypertensive effect, since it would not release NO readily. Using a recombinant Hb with a destabilized T-state (and therefore high oxygen affinity), it could be shown that the hypertensive effect is in fact independent of p_{50} and cooperativity. Additional experiments showed that the thiol groups on the injected Hbs remained free. Other results have equally cast doubt on the hypothesis that Hb serves as a NO carrier; for example, the amount of *S*-nitrosohemoglobin found *in vivo* is very low, and escape from the red cell would be very difficult for NO due to the high concentration of reactive hemes present. Attention has now focused away from cysteine 93β. The recombinant Hb-based artificial oxygen carriers therefore seem to have a considerable advantage over formulations based on human or animal blood, since the NO reactivity may be significantly reduced while preserving the desired oxygen-binding characteristics. The Olson group has used recombinant Mb as a test system in order to find mutants around the heme, which can inhibit NO binding while allowing oxygen to bind freely. Similar work by the group of professors Brunori, Chiancone, and Vallone in Rome has also shown that residue B10 exerts control over ligand selectivity. By replacing Leu B10 with tyrosine and His E7 with glutamine, the Rome group showed that NO binding could be reduced significantly while allowing oxygen to bind.

Recent research from the group of Yonetani has indicated, however, that natural Hbs carrying NO on the α-subunits (which have higher NO affinity than the β-subunits) may overcome the problem of hypertension. A number of commercial enterprises are continuing to work hard since many years to find a chemical modification to convert natural Hb into a safe, sterile alternative to present-day blood transfusions. The problems with this technology are highlighted by at least one company that is investigating methods of removing A and B type

antigens from red blood cells to allow "typeless" transfusions. Stockholders in such a company are clearly betting that recombinant Hb research does not solve the clinical problems quickly.

8.2
96α Val→Trp

Another artificial Hb with low oxygen affinity but high cooperativity has been investigated by the Ho group in the hope of finding a clinically useful oxygen carrier. This is the 96αVal→Trp mutant. Molecular dynamics simulations suggested that the indole side chain of the tryptophan might interact with 99β Asp, but the crystal structure later showed that instead it points into the central cavity and forms hydrogen bonds with 101βGlu. (Hb seems to provide too stern a test for molecular dynamics at present). Combining this mutation with the Asn 108β→Lys mutation of Hb Presbyterian gives a recombinant Hb with even lower affinity, which retains cooperativity. Unfortunately, it also oxidizes very easily. A third (29αLeu→Phe) mutation was added in an attempt to slow-down oxidation, but had limited effect. Analysis of this triple mutant was complicated by the appearance of *bis*-histidine hemichrome, and overall the tetramer was significantly destabilized.

9
Animal Hemoglobins

Globins are found in an enormous variety of organisms including bacteria, yeast, plants, and vertebrates. Their evolution has been the subject of numerous discussions, and the protein family clearly has a very ancient lineage. In the course of vertebrate evolution, Hbs have appeared with different functional properties. Not all animal Hbs use DPG (as human Hb does) as an allosteric effector. Some fish Hbs use ATP, rhinoceros Hbs use GTP, and cat and sheep Hbs use no such effector at all. These different properties can be explained by mutations found at the DPG binding site of human Hb. Other properties of animal Hbs are less easily explained, and site-directed mutagenesis has been used to investigate them by mutating human HbA.

9.1
Geese

Animals living at high altitudes have developed Hbs with high oxygen affinity to extract oxygen from the thinner atmosphere. This is particularly true of high-flying birds such as bar-headed geese, which migrate over the Himalayas at altitudes of around 10 000 m. The closely related greylag goose has Hb with an oxygen affinity much closer to that of HbA. Sequence comparison between the two Hbs revealed only four amino acid changes. Perutz predicted that the increase in oxygen affinity would be found to be due to a single mutation, Pro 119(H2)α→Ala. This residue forms a contact with D6β (which is leucine in bar-headed goose but methionine in man) at the $\alpha_1\beta_1$ subunit interface. All mutations that disrupt such contacts destabilize the T-state relative to the R-state. The prediction was confirmed by engineering this mutation into human Hb using the Nagai and Thøgersen expression system. Jessen and coworkers demonstrated that the mutant Hb shows the same increase in oxygen affinity as bar-headed goose Hb compared to greylag goose. From the X-ray crystal structure, it is clear that the mutation has caused only localized effects and not a gross change

in the molecule. Interestingly, the Andean goose, which flies across a mountain chain in another continent, has evolved a Hb in which the D6β residue is changed to serine. This breaks the same contact and leads to the same increase in oxygen affinity.

The combination of the known molecular structure of human Hb and the sequences of the two highly related goose Hbs allowed Perutz to predict which was the functional mutation. Unfortunately, it has generally not proved possible to predict or explain so easily the unusual properties of a number of animal Hbs.

9.2 Fish

Within physiological conditions, human Hb shows a decrease in oxygen affinity as pH falls, a phenomenon called the *alkaline Bohr effect*. The cause of the Bohr effect has been the subject of numerous studies, but a recombinant Hb was used by the Nagai group to confirm the major role of His 146β. Many bony fish Hbs show an exceptionally strong alkaline Bohr effect, known as the Root effect after its discoverer. Oxygen affinity drops sharply and oxygen binding becomes noncooperative as the pH is lowered to about 6 or less. The effect has an important physiological function, namely, supplying oxygen to the swim bladder and the eye. Both these organs secrete lactic acid into the bloodstream, which then discharges oxygen. It was suggested by Perutz that this increased stabilization of the T-state relative to the R-state by hydrogen ions is due to a single mutation, Cys 93(F9)$\beta \rightarrow$ Ser. The serine hydroxyl group was thought to form a hydrogen bond with the terminal histidine, His 146β in the T-state. This histidine forms a salt bridge with Asp 94β in T-state, but not R-state, HbA.

Perutz's idea was tested by Luisi and Nagai in Cambridge, who made a series of human Hb mutants with the Nagai and Thøgersen system. The mutations Cys 93$\beta \rightarrow$ Ser and His 143$\beta \rightarrow$ Arg were introduced sequentially. Both reduced the Bohr effect. Additional changes, Asp 94$\beta \rightarrow$ Glu, His 144$\beta \rightarrow$ Gln, His 2$\beta \rightarrow$ Glu and Glu 90$\beta \rightarrow$ Ser, did lead to an increase in the Bohr effect, but the overall oxygen affinity of the final mutant is much higher than that of native fish Hbs.

The X-ray crystal structures of Hb from the Antarctic fish *Pagothenia bernachii* (now renamed *Trematomus bernachii*) have been solved in both the deoxy T-state and the carbonmonoxy R-state, but unfortunately these provide few clues to the groups responsible for the pH dependence of the allosteric equilibrium. A pair of close carboxyl groups was suggested to destabilize the R-state under acid conditions, but cannot alone be responsible for the very low oxygen affinity found at low pH. Furthermore, the deoxy structure shows that the C-terminal β-chain histidine residue does not form a salt bridge equivalent to the one found in human Hb. This was a considerable surprise since this salt bridge is a major contributor to the pH dependence of human Hb. It seems, however, that there are a number of different groups, which can cause the Bohr or Root effects.

The R-state structure of another Root effect Hb, from a fish called *spot*, has also been solved by Mylvaganam and coworkers from which it was suggested that the effect is in fact caused by destabilization of the R-state rather than stabilization of the T-state. However, the major Hb from *Trematomus newnesi*, a close relative of *T. bernachii* is only different at 14 residues from *T. bernachii* Hb but has almost no

pH dependence at all. It also has all the residues suggested to destabilize the R-state at low pH. Clearly, the Root effect could not be solved by simple examination of the models, so the Nagai group in Cambridge has produced more mutants attempting to transfer the Root effect from *T. bernachii* Hb to *T. newnesi* Hb, but so far without success. The final proof of any proposed mechanism will be its transplantation into human HbA by mutagenesis.

9.3 Crocodiles

Uniquely among vertebrate Hbs, the principal allosteric effector of crocodile Hb is not an organic phosphate but bicarbonate ions, which strongly stabilize the T-state. Two bicarbonate ions bind to each Hb tetramer, lowering the oxygen affinity as much as IHP does in HbA. This effect is possibly related to the ability of the crocodile to remain submerged for long periods. It was suggested by Perutz that the DPG binding site of human Hb has been modified by three or four mutations to create a pair of bicarbonate ion binding sites related by the molecular twofold axis. Site-directed mutagenic experiments based on this hypothesis have failed to transplant bicarbonate binding, however.

An alternative site was proposed at the β-subunit C-helices, which form a sliding contact with the α-FG corners. Crocodile Hbs show two more positive charges than HbA in this highly conserved region of the molecule. A number of experiments to identify the true bicarbonate binding site have been carried out using the expression vector described by Hoffman et al. This work involved mixing crocodile-like and normal human globins to create mixed tetramers, conclusively showing that the bicarbonate binding site is found in the β-subunits. It has now been demonstrated that the bicarbonate effect is introduced into human Hb by mutations in the C-helix, but additional mutations in the α-subunit are required to maintain cooperative oxygen binding. A total of 12 mutations were introduced into human hemoglobin to confer the bicarbonate effect. The resulting mutant, called Hb Scuba, shows the same bicarbonate effect as native crocodile Hb. Crocodile Hbs have one of the mutations mentioned earlier at the C7 position, Phe 41β→Tyr, and it is believed the bicarbonate hydrogen bonds to this residue (Fig. 3). Hb Scuba has now been crystallized and further research is underway to investigate its properties.

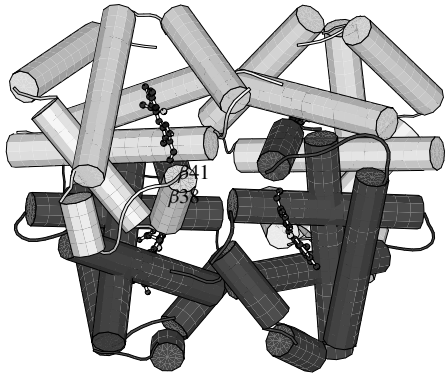

Fig. 3 A diagram of the Hb tetramer with the α-chains shown in dark gray and the β-chains shown in light gray. The 38β and 41β residues are implicated in the bicarbonate binding by crocodile Hbs, but a precise stereochemical model of this interaction has yet to be worked out.

So far, Hb Scuba is perhaps the most dramatic result from the Hb engineering, but it demonstrates that the evolution of new ligand binding sites may require more than the three or four mutations envisioned by Perutz or Kimura's ''neutral hypothesis,'' and some of these may not have an obvious relevance from the molecular model of the protein.

10 Evolution

Genetic engineering has not only allowed us to probe the workings of the protein, but also allowed us to understand its evolution better. Hb evolution has attracted a great deal of interest because there is so much sequence data available for globins from many different species, and the structures of several of these proteins are known. The α- and β-globin genes appear to have diverged from a common ancestor around 500 million years ago. Although very similar, vertebrate α-globin has no equivalent of the D-helix in β-globin (Fig. 4). Human α-globin is therefore 5 amino acid residues shorter than β-globin. Two mutants were made by Komiyama and colleagues to test the functional role of the D-helix, one with the helix removed from the β-subunits and one with the same sequence inserted into the α-subunits. The Hoffman expression vector was used to synthesize the proteins as functional tetramers with a valine to methionine mutation at the N-terminus of each subunit. Both proteins, αD^{+} and βD^{-}, folded and incorporated heme within the cell. Neither the insertion nor the deletion appreciably affected the oxygen affinity or cooperativity of oxygen binding – a remarkable demonstration of how robust the protein is to mutation. The Olson group has shown, however, that the loss of the D-helix does destabilize the βD^{-}-subunit, which loses heme more readily than the native protein. Although neutral to ligand binding, removal of the D-helix from the β-subunits is an unfavorable mutation for the organism.

11 Nuclear Magnetic Resonance Spectroscopy (NMR)

In the last few years, both X-ray crystallography and macromolecular NMR have

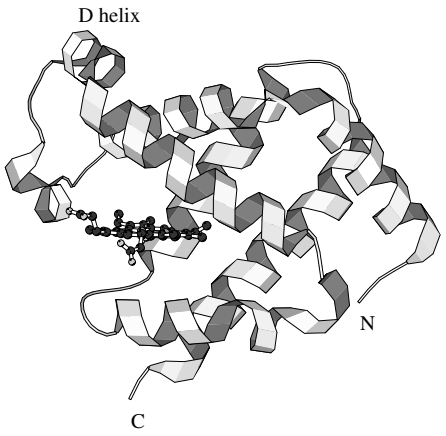

Fig. 4 The tertiary structure of β-globin, showing the extra D-helix not found in the α-chain. Apart from the D-helix, the overall structure of α- and β-globins is very similar. Deletion of the D-helix from the β-subunits and its insertion into the α-subunits still gives a functional Hb tetramer with cooperative oxygen binding.

been transformed by improvements in hardware and software. 800 MHz NMR magnets are now relatively common at protein research facilities, and 900 MHz machines are available, at a cost. Improvements in magnets and probes have now brought much larger proteins within the sphere of NMR, provided that they can be isotopically labeled appropriately. In the 1970s and 1980s, NMR was restricted to studies of the heme pocket or histidine residues of Hb. This work included some key work by the Ho group on the Bohr effect, which was a subject of considerable controversy.

In healthy humans, the pH of the blood is very tightly controlled within strict limits. Hb can, however, respond to small local changes in pH brought about by metabolism; decreases in pH lower the oxygen affinity, a phenomenon called the *alkaline Bohr effect* or, more usually, simply *the Bohr effect*. In fact, in 1904, Bohr discovered the drop in oxygen affinity with increased levels of carbon dioxide, five years before the concept of pH was put forward. The so-called *acid Bohr effect*, the decrease in oxygen affinity with rise in pH, is only seen at unphysiologically low pH for human Hb. The Bohr effect is expressed as the number of hydrogen ions released upon oxygenation (there is an absolute thermodynamic relationship between the change in oxygen affinity and the number of hydrogen ions taken up on oxygen binding). Histidine side chains have a pK close to neutral, and, therefore, are often able to bind or lose protons as their environment in protein changes. Proton NMR is extremely useful for studying the Bohr effect since the histidine resonances are often separate from other peaks in the spectrum. Furthermore, it is possible to find the pK of these histidines by titration, measuring the shift in peak positions with pH. One difficulty with this approach, however, is in assigning the resonances to the correct residues. Although many histidines could be assigned with confidence, marked disagreements also occurred. Using artificial Hb mutants, the Ho group has now completed the assignment of all surface histidine residues and measured their pKa values. These 24 residues account for 86% of the Bohr effect at pH 7.4 in 0.1 M chloride.

More recently, however, the Ho group has produced N^{15} isotopically labeled human HbA for analysis by NMR. This is an exciting development, which will allow us to analyze in much greater detail the protein in solution. For the majority of proteins, there is little doubt that crystal structures reflect the structure in solution quite faithfully – enzymes are still active in the crystal, and different crystal forms of the same protein but with different neighbor contacts show very similar structures. In the case of an allosteric protein such as Hb, there is the possibility that the crystallization might disturb the allosteric equilibrium, and select one allosteric form from a range of energetically similar conformations in equilibrium in solution. A new conformation of HbA was found in the early 1990s, called the *R2 state*. Within a few years, several papers appeared in which it was suggested, more or less strongly, that this might better reflect the ''true'' structure of HbA. In particular, this crystal form was grown from polyethylene glycol instead of ammonium sulfate, and the belief grew that the ''high salt'' conditions used by Perutz to make oxyHb and metHb crystals might inhibit Hb from undergoing the complete allosteric transition. A short article

in 1999 by the author critically reviewing the evidence each way suggested that obituaries of the R-state seemed premature. This drew a heated response from Mueser and colleagues, but crystallography alone is not able to test the solution state of a protein, and the case against the R-state remains weak at best. Recently, Lukin and colleagues have used isotopically labeled HbA to assess how well the NMR data agree with the R and R2 crystal structures. Under the conditions used, 0.1 M sodium phosphate at pH 7.0, it was found that a structure intermediate between the two fits the data best. NMR will no doubt play a large role in future Hb research.

12 Summary

Clearly, it has proved difficult to judge the functional roles of residues in Hb from the crystallographic structures alone, even where these are refined to high resolution in different ligation states. The functional properties of individual parts of the protein can be tested only by synthesizing mutants and analyzing the differences between them and HbA. Although the different effects on oxygen affinity of the valine E11 side chain were predicted correctly, the relative affinities of the α- and β-subunits for ligands were not. Despite many years of research, there is still much to learn about the nature of cooperative oxygen binding and the pathway by which deoxy Hb switches to oxy-Hb and back again. Site-directed mutagenesis continues to play an important role in this research; in fact, protein expression systems allowing folded, tetrameric Hb to be produced directly have led to a renaissance in the field.

While many clinically observed Hb mutations have shown that alteration of surface residues rarely affects too drastically the physiological properties of the protein, it is still remarkable that these changes produce so little effect. The tolerance of the globin fold to residue changes no doubt accounts for its evolutionary success. This property, fortunately, also gives us the opportunity to alter much of the sequence and still produce a functional protein, allowing many more mutants of interest to be made. While Hb is often presented in a rather ''cut-and-dried'' fashion in biochemistry textbooks, there remain a number of unsolved issues, and, no doubt, artificial mutants will be needed to resolve them.

Keywords

Adjuvant Genes
Genes (often cytokine genes) that are used for the enhancement of the efficacy of recombinant vaccines.

Attenuating Genes
Genes that are used to enhance the safety of vaccines or vectors by reducing the virulence of agents.

Baculovirus
An insect virus widely used for abundant and inexpensive generation of recombinant proteins in insect cells or larvae.

Chimeric
Describing a fusion product of two or more genes or polypeptides often retaining the activities of both proteins.

Recombinant
An organism, nucleic acid, or proteins generated by genetic engineering.

Vaccinia Virus
An *orthopoxvirus* of uncertain origins causing no known disease that provides protective immunity against a number of *orthopoxvirus* infections, including smallpox.

Vector
A bacterium, virus, or a plasmid that is used for the introduction of nucleic acid (typically DNA) molecules for the generation of recombinants.

Using the techniques of molecular biology, effective modern vaccines are being developed by a variety of innovative methods that circumvent some of the problems associated with conventional vaccines. Live recombinant vaccines, which are prepared by isolating an immunogenic gene(s) from a disease organism and inserting it into a vector, are most promising. Such vaccines can provide immunity to agents that cannot be reliably attenuated or inactivated without destroying immunogenicity and allow one to distinguish vaccinated from infected animals.

1 Introduction

Over the past century, the gradual accumulation of knowledge concerning contagion and immunity has led to great advances in our ongoing struggle against infectious disease. In an effort to gain protection from the most serious infections, we have progressed from the earliest type of quarantine (the shunning of the obviously ill) to deliberate, though controlled and limited, exposure to an attenuated disease agent. One of the earliest examples of such exposure is seen in the battle against the dreaded scourge, smallpox. The dangerous and sometimes deadly practice of variolation – a deliberate exposure to the lesions of human cases in hopes of contracting a mild form of the disease – was practiced sporadically for centuries before the fortuitous discovery of the protection afforded by related, less virulent strains of virus. By 1796, Dr. Edward Jenner had begun to carefully introduce pox pustular material from cowpox lesions into his patients' skin – a process called vaccination – to protect against smallpox. The latter half of the nineteenth century brought an explosion of discoveries in immune protection, with specific vaccines produced for a wide variety of human and animal diseases. Over time, many of the most serious of human disease threats have retreated as a result of the advances of classical vaccine therapy.

Classical vaccines have generally been of three types: live attenuated agents, inactivated (killed) agents, or their modified toxins (toxoids). Vaccinia virus (VV), the poxvirus strain that protects human beings from smallpox, was attenuated naturally during its adaptation to different species. From the time of Pasteur and Koch, laboratories have worked to produce other attenuated disease agents (by varying their conditions of growth and maintenance or multiple passages through a different host species) or to find nonvirulent, protective strains in nature. To produce effective vaccines of some disease agents, it has been necessary to attempt inactivation of the agent by heat or chemicals, often destroying the nucleic acid while retaining the protein or carbohydrate components of the agent, thus eliminating its capacity for growth or replication while retaining the protective, immunity-inducing antigens.

The live attenuated and inactivated vaccines each have their advantages and disadvantages. Inactivated vaccines are usually easier to produce and are the only protection available against certain diseases. Protection against diseases caused by secreted toxins can be similarly accomplished by using heat or chemicals to convert these to toxoids, without toxicity but still immunogenic. However, the optimal dose of inactivated antigens must be provided for effectiveness, and even then these vaccines are poor inducers of cell-mediated immunity (CMI). Additionally, although thorough inactivation relieves safety concerns, there have been instances of diseases resulting from incomplete inactivation of an agent. Thus, inactivated vaccines often are less effective than live attenuated vaccines because live vaccines have the capacity to reproduce or replicate in the host organism, amplifying the antigen, and are excellent inducers of CMI. This amplification effect increases the stimulus to the immune system and may elicit a better immune response by providing optimal amounts of antigen. Maintaining live cultures and producing live vaccines, however, is much more demanding, requiring special laboratory and transport facilities. Many live vaccines

are heat labile and must be refrigerated, further complicating their use in remote areas. Other safety concerns also arise with live vaccines because attenuated strains may revert to virulence in the vertebrate host or an arthropod vector, new strains of the agent may arise from the vaccine strain, or the vaccine may actually induce the disease in pregnant or debilitated animals.

A further serious disadvantage of classical vaccines is that, whether live or killed, they contain whole disease agents that elicit a full range of immune responses. Thus, with very few exceptions, one cannot develop a serological test for distinguishing animals vaccinated with either live attenuated or inactivated vaccines from those recovered from natural infections. This is an important consideration in epidemiological studies, animal disease diagnosis and control, as well as in economics. Restrictions on the export/import of animals and their products because of positive antibody tests can result in substantial economic losses.

Advances in molecular biology in the last thirty years have given rise to a remarkable new generation of vaccines that includes subunit, synthetic peptide, live recombinant, and DNA vaccines. These advances include the identification of an agent's specific, immunity-inducing molecules, the synthesis of all or the active portions of these molecules, and the incorporation of the responsible immunogenic genes into the genome of a nonvirulent carrier or vector agent. A wide variety of vaccines are now being developed for use and may greatly improve our ability to protect against infectious diseases. Live recombinant vaccines, in particular, appear to hold great promise for continuing improvements in disease control.

2
Recombinant Vaccines

2.1
Vectors

Recombinant DNA technology now makes it possible to retain most of the advantages of live vaccines, while overcoming many of their inherent safety hazards and logistical disadvantages, by inserting and expressing heterologous genes in a variety of different viruses. Both DNA and RNA viruses are used extensively as expression vectors. Although the relatively small size of most of these viruses facilitates genetic engineering, this property also restricts the amount of DNA that can be inserted into the virus particle. In addition, many of these virus vectors have a limited host range that does not allow their replication in the vaccine's target species. They may be defective, requiring either a helper virus or special cell lines for their replication. Furthermore, many of these vectors are oncogenic and therefore may be unsuitable for use as vaccines in humans and domestic animals.

2.2
Vaccinia Virus

The disadvantages of the vector systems can be overcome by using VV as a vector and by creating a live recombinant vaccine with the immunogenic genes of disease agents incorporated into the VV genome. When the VV vector is introduced into an animal, the virus replicates in the host's cells and the foreign genes are expressed along with those of VV; thus, the animal becomes immune both to VV and to the agent from which the foreign gene was taken. The history of VV in human hosts attests to its safety: during this past century, the VV vaccination procedure has

protected hundreds of millions of people worldwide from smallpox, with minimal side effects and no adverse environmental impact, despite global release of the VV under varying hygienic conditions. Vaccination with this virus has been achieved by scarification (light scratching of the skin), by subcutaneous or intramuscular injection, and by intranasal or even oral administration. It can be grown outside the laboratory by scarification of the abdomen of a single calf to prepare more than 200 000 vaccine doses – a great advantage for use in developing countries. The virus is heat stable, particularly in the lyophilized state, and it can be reconstituted easily. Modern vaccine technology now gives us, through genetic engineering, the capability of using VV as a live vector to protect animals and people against other unrelated, disease agents.

A member of the poxvirus family, VV is a large, double-stranded DNA virus that packages a complete transcription system and replicates in the cytoplasm of infected cells. The virus has a wide host range that includes humans, cattle, horses, swine, sheep, goats, mice, and monkeys, making it useful for both human and a variety of animal vaccines. Its large genome can accept more than a dozen heterologous genes, opening the possibility of producing a multivalent vaccine that could protect against several diseases with one administration. The molecular biology of the virus is well documented and supports the engineering techniques necessary for producing, isolating, and identifying recombinants. The genome contains more than a dozen nonessential regions that can be used for incorporation of foreign antigen genes and reporter genes that assist in identifying the desired recombinants, in addition to the commonly used viral marker, the *TK* (thymidine kinase) gene. Using recombinant DNA technology, convenient marker rescue techniques and plasmid vectors containing homologous sequences to the virus DNA have been developed that allow recombination within infected cells.

2.3 Genetic Engineering

The application of recombinant DNA technology to constructing recombinant VVs utilizes convenient marker rescue techniques and plasmid vectors containing homologous sequences to the virus DNA, allowing recombination within infected cells. The strategy for using VV as a vector (as shown in Fig. 1) involves first constructing a plasmid carrying a foreign (heterologous) gene. This unit consists of a VV promoter fused to a foreign-protein-coding sequence that is flanked by DNA from a nonessential region of the VV genome. The chimeric gene is incorporated into the VV genome by homologous recombination in tissue culture cells that have been infected with wild-type VV and then transfected with the plasmid. Although any nonessential region of the VV genome can be used as the site of gene insertion, the thymidine kinase gene locus provides some advantages because recombinants are then TK^-. The TK^- phenotype serves to attenuate viral pathogenicity, and also can be easily distinguished from wild-type TK^+ virus by 5-bromo-2′-deoxyuridine (BrdU) selection. Rapid screening of recombinants of interest can also be facilitated with the co-expression of reporter genes, such as the *Escherichia coli* β-galactosidase (*lacZ*) gene. Expression of the *lacZ* gene results in a blue coloration in the presence of 5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside (X-Gal); one is thereby

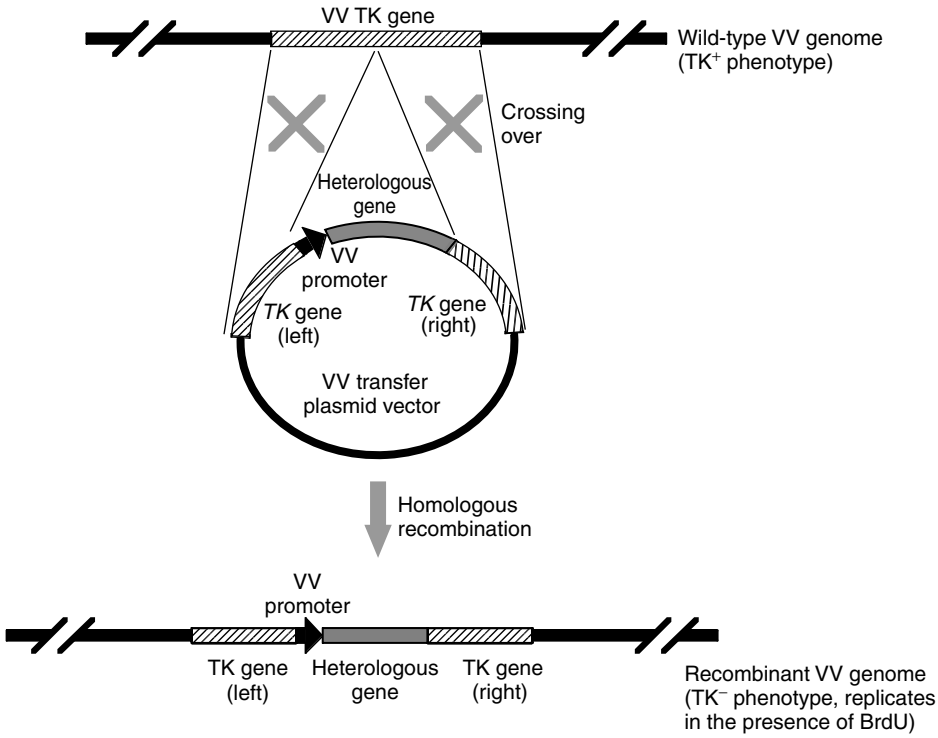

Fig. 1 Construction of recombinant VV vaccines by homologous recombination. The VV transfer vector contains the VV *TK* gene insertionally inactivated by a foreign (heterologous) gene under the control of a VV promoter. Upon infection of cells in tissue culture with the wild-type VV (TK^+ phenotype) and transfection of the same cells with the transfer vector, a double crossing-over event may occur between the homologous sequences in the transfer vector and the VV genome. This results in the transfer of the heterologous gene under the VV promoter to the VV genome, and the insertional inactivation of the *TK* gene. Recombinant VVs are selected from wild-type viruses by serial plaque assays in TK^- cell lines in the presence of BrdU. TK^- cells infected with wild-type VV (with TK activity) are able to phosphorylate BrdU and lethally incorporate this thymidine analog into the VV genome. TK^- cells infected with recombinant VVs (without TK activity) are unable to incorporate BrdU into the VV genome and as a result, progeny viruses are viable.

able to distinguish recombinants from wild-type virus by their blue plaque phenotype.

3 Vaccinia Virus Recombinant Vaccines

A description of three VV recombinants that we have constructed and used with varying degrees of success as vaccines will illustrate the potential of these agents: a vaccine for rinderpest that induced 100% protection against a challenge greater than 1000 times the normally lethal dose, a vaccine for vesicular stomatitis that was moderately successful in protecting against the disease, and a vaccine for simian immunodeficiency virus (SIV) that did not prevent infection but significantly

reduced the virus load from control levels and delayed the onset of clinical disease.

3.1 A Vaccinia Virus Recombinant Vaccine for Rinderpest

Our most successful VV recombinant vaccine is one developed for rinderpest virus (RPV), the causative agent of the single most important viral disease of livestock in developing countries. An acute, febrile, highly contagious viral disease of ruminants (particularly cattle and buffalo) with a rapid course and a mortality rate exceeding 90%, rinderpest is characterized by inflammation, hemorrhaging, necrosis, and erosion of the gastrointestinal tract accompanied by bloody diarrhea, wasting, and death. This disease was controlled in Africa in the 1970s by an international effort called the Joint Project/15 (JP/15), which vaccinated 124 million cattle, but recent resurgences have necessitated a second Pan-African Rinderpest Campaign, currently in progress.

Continuing outbreaks of rinderpest have pointed out the logistical difficulties of reliance on live vaccines in the regions where this disease is prevalent, but the vaccine currently in use, the Plowright tissue culture rinderpest vaccine (TCRV) for rinderpest, is an attenuated, live vaccine with the limitations common to such preparations. It is extremely heat labile and requires maintenance of a cold chain; in most instances, the vaccine must be used within 30 minutes of reconstitution to ensure potency. TCRV is effective, but the requirement of skilled personnel for vaccine preparation and administration and a need for refrigeration facilities – often lacking in the hot and isolated areas in which the disease is prevalent – are obstacles to its use.

A VV recombinant vaccine for rinderpest, many felt, would provide an alternative and circumvent many of the obstacles limiting the use of TCRV. The heat-stable lyophilized form of VV is easily produced, stored, and transported; and it can be administered by a number of routes including scarification, intradermal, intramuscular, subcutaneous, and oral. It is possible, as was shown in the smallpox eradication campaign, for each independent area to carry on vaccine production by collecting and emulsifying scabs from vaccinated animals for use as needed. The self-sufficiency thus afforded to local animal handlers is a rare and valuable empowerment for developing countries that frees them from reliance on international assistance. For these reasons, a VV recombinant vaccine for rinderpest is a valuable addition to the arsenal of defense and raises the possibility of eradicating this disease. Our efforts to construct such a vaccine have had a highly successful conclusion: we have produced one of the two most effective recombinant vaccines to date. Our rinderpest vaccine, which was designated as a prototype for genetically engineered vaccines for export, has been approved for field trials in Kenya and Ethiopia by the U.S. Department of Agriculture/Animal and Plant Health Inspection Service and the U.S. Agency for International Development. The other successful agent is a recombinant VV vaccine for rabies, currently being extensively used to eradicate sylvatic rabies in Europe and North America.

The causative virus of rinderpest is enveloped and has a single-stranded RNA genome with a minus polarity. It is in the family *Paramyxoviridae* and is a member of the morbillivirus genus along with measles virus of human beings, distemper virus of dogs, and peste-des-petits-ruminants virus

(PPRV) of goats and sheep. We propagated the highly virulent Kabete "O" strain of RPV in primary bovine kidney cells and characterized eight viral proteins. We made cDNA copies of the phosphoprotein (P), hemagglutinin (H), fusion (F), and nucleoprotein (*N*) genes and determined the complete nucleotide sequence of these genes. In all paramyxoviruses, the H and F surface proteins elicit protective immunity. Standard procedures were used to construct VV recombinants expressing the H gene (vRVH) or the F gene (vRVF) of RPV.

Using these VV recombinants (vRVH and vRVF), protective immune response studies in cattle were conducted in the high containment facility at the Plum Island Animal Disease Center. Each animal was shown to be seronegative to RPV prior to vaccination, and 10^8 plaque-forming units (PFU) of the VV recombinant vaccine was administered in a single vaccination by intradermal inoculation and scarification. Groups of five animals received either one recombinant (vRVH or vRVF) or a mixture of both recombinants (vRVH + vRVF). Two animals were vaccinated with TCRV as positive controls, and two were left unvaccinated as negative controls. For a VV control, two animals were vaccinated with v50, a VV recombinant expressing the glycoprotein gene of the vesicular stomatitis virus (VSV).

Pock lesions developed as early as four days in all animals vaccinated with the recombinants, but were limited to the site of inoculation and healed completely by two weeks. Humoral responses to the vaccines were assessed by serum neutralization (SN) assay. All animals vaccinated with the recombinants or TCRV produced SN antibodies to RPV. As expected, control animals had no detectable antibody titer.

To evaluate protection, all animals were challenged subcutaneously with a heavy dose (10^3 $TCID_{50}$—tissue culture infectious dose for 50% of subjects) of RPV in the prescapular lymph node region on day 35 following primary immunization. As low as 1 $TCID_{50}$ induced clinical rinderpest with 100% mortality. Cattle vaccinated with the recombinants or TCRV were completely protected when challenged, even though the inoculation was greater than 1,000 times a lethal dose of RPV. Some of the cattle, most of these vaccinated with the F recombinant (vRVF), had strong anamnestic responses to RPV after challenge inoculation; this indicated replication of the challenge virus. No anamnestic response could be demonstrated in the groups vaccinated with the mixture of both recombinants and TCRV, indicating little or no challenge virus replication.

Viral infection and spread are mediated by receptor binding (to H) and membrane fusion (by F), so it is reasonable to expect a vaccine preparation containing both antigens to be superior to one containing the H- or the F-glycoprotein alone. Vaccinating with the vRVF + vRVH mixture in the field, however, is cumbersome and expensive, and particularly burdensome for developing countries. For this reason as well as to obtain greater standardization and more reliable results, we decided to include both genes in a single recombinant. Using techniques similar to those described earlier, we developed a VV (Wyeth strain) double recombinant that includes both the *F* and the *H* genes (vRVFH) of RPV; this recombinant expresses the authentic RPV F- and H-proteins. The *F* and *H* genes were inserted into the *VV TK* and *H* gene regions, respectively, thus inactivating these *VV* genes and giving an even more highly attenuated VV recombinant vaccine. Indeed, cattle vaccinated with this

double recombinant (vRVFH) had no pock lesions at the site of inoculation, indicating a high degree of attenuation.

Cattle were vaccinated with 10^8 PFU of vRVFH by intradermal inoculation in the neck region. Two groups of cattle were vaccinated with VV recombinants and kept in separate isolation rooms. In the first group, five animals were vaccinated with vRVFH. In the second group, four animals were vaccinated with a mixture of vRVF and vRVH. In addition, two unvaccinated animals were housed with each group, to assess the transmissibility of VV recombinants from vaccinated to contact animals. Unlike animals vaccinated with the mixture of vRVH and vRVF, those vaccinated with vRVFH developed no detectable pock lesions; a thorough examination failed to demonstrate pock lesions in the contact animals in both groups. Further, serum samples taken from contact animals on the days of vaccination (day 0) and challenge (day 28) were negative to VV by SN and plaque reduction assays. All cattle vaccinated with the recombinants produced SN antibody to RPV as early as eight days after vaccination. However, all contact and control animals lacked detectable SN antibody to RPV during the course of the experiment.

One month postvaccination, all animals in both groups were challenge-inoculated with 10^3 $TCID_{50}$ of the pathogenic Kabete "O" strain of RPV. Cattle vaccinated with VV recombinants (both groups) were completely protected from rinderpest, exhibiting no detectable illness and a normal temperature of 38 °C. The four unvaccinated contacts developed high fever (42 °C) by day 2 and died by day 6 after challenge, showing lesions typical of severe rinderpest. Daily monitoring for two weeks showed no detectable clinical disease in vaccinated animals, and the experiment was terminated. In a confined field trial in DebreZeit, Ethiopia, the vaccine was shown to be effective for at least one year postvaccination.

We have also tested vRVFH and the parental Wyeth strain for pathogenicity by inoculating immunodeficient nude mice intraperitoneally, and no clinical disease was detected in 12 test mice. In addition, we assessed the effects of vRVFH and the mixture of single recombinants (vRVF + vRVH) on the immune systems of rhesus macaques infected with the simian immunodeficiency virus (SIV). These monkeys suffer from an immunodeficiency disease virtually identical to the human acquired immunodeficiency syndrome (AIDS). Hence, SIV is a legitimate model for HIV. Four normal macaques and four SIV-infected macaques were vaccinated with vRVFH. Apparently, the lack of development of pock lesions in cattle vaccinated with vRVFH is host specific; both groups of monkeys developed small pock lesions at the site of inoculation, but these healed completely by two weeks postvaccination. No clinical disease or dissemination of VV was observed in either normal or SIV-infected macaques during a one-month observation following vaccination.

More recently, we have developed a second-generation recombinant VV vaccine (v2RVFH) that induces both humoral immune responses and protective immunity comparable to those elicited by TCRV. We enhanced efficacy by using strong synthetic promoters to increase the expression of the *F* and *H* genes of RPV. Moreover, we added the *lacZ* gene to serve as an easily identifiable marker to aid in recombinant VV selection during the development of the vaccine, and more importantly, to distinguish the vaccine virus (v2RVFH) from

other naturally occurring poxviruses during vaccination programs.

Compared to vRVFH or the single recombinants expressing F or H, v2RVFH displays a distinct plaque morphology in cell culture that is characterized by the formation of massive syncytia due to higher levels of expression of both glycoproteins. Radioimmunoprecipitation studies showed that the band intensities for the F- and H- proteins expressed by v2RVFH were at least threefold higher than those generated by vRVFH or the single recombinants. We conducted short- and long-term safety and efficacy studies in African cattle, and demonstrated that as little as 10^2 PFU of v2RVFH, given intramuscularly, protects 50% of the vaccinated cattle from virulent challenge with RPV. Unlike the intradermal route, the intramuscular route facilitates mass vaccination of cattle under field conditions. We also showed that a dose of 10^8 PFU of v2RVFH induced levels of SN antibodies to RPV comparable to those elicited by TCRV, and that this dose provides sterilizing immunity to cattle for at least two years postvaccination. This level of protection suggests that v2RVFH confers long-term immunity equivalent to TCRV. Lastly, v2RVFH is not only highly efficacious but also safe, since it is attenuated by the insertional inactivation of the *TK* gene. As a result, no pock lesions were detected after vaccination, and there was no lateral transmission to contact animals.

Rinderpest appears to be an excellent candidate for eradication using the VV recombinant vaccines. There is only one serotype of RPV, although there are different strains manifesting different degrees of pathogenicity in the field. A vaccine against one strain will immunize against all, including peste-des-petits ruminants virus (PPRV) of sheep and goats. Use of the rinderpest recombinant VV vaccines in areas of the world where PPRV is endemic would also aid in the control and eradication of PPR.

3.2 Vaccines for Peste-des-Petits Ruminants

Peste-des-Petits Ruminants (PPR) is a disease of small ruminants caused by a virus (PPRV) closely related to RPV of cattle. The disease is characterized by necrotizing and erosive stomatitis, enteritis, and pneumonia. Morbidity and mortality are very high, and the virus is a serious health problem in small ruminants in Africa and the Middle East. Although cattle can be infected with PPRV, they do not exhibit clinical disease. Vaccination of goats with vRVFH provided complete protection against a challenge-inoculation with 10^3 $TCID_{50}$ of PPRV.

All goats used in these experiments were determined to be seronegative to PPRV and RPV at the start of the study. Eight goats were vaccinated with 10^8 PFU of vRVFH by intradermal inoculation and scarification. For controls, six goats were vaccinated with the parental VV (Wyeth strain). On day 35 postvaccination, goats were challenge-inoculated with 10^3 $TCID_{50}$ of PPRV, strain Mieliq-Sudan, by subcutaneous injection just anterior to the prescapular lymph node. Serum was collected on days 0, 35, 42, and 56, and titers to RPV and PPRV were determined by SN and by ELISA (enzyme-linked immunosorbent assay). Antibody directed to the F-protein was measured by ELISA only, because the glycoprotein is not the antireceptor of the virus and does not usually induce SN antibody. Goats vaccinated with vRVFH had SN (32–512) and ELISA (2–16) titers to RPV and undetectable SN titers to PPRV by

day 35 postvaccination. Anti-PPRV ELISA titers of vaccinated goats were undetectable in four goats and low (2, 2, 2, and 8) in the remaining four goats on the day of challenge.

All control animals lacked detectable SN and ELISA titers to either PPRV or RPV on the day of challenge. After challenge inoculation, however, there was a strong anamnestic response, as indicated by high SN and ELISA titers. In contrast, the postchallenge ELISA titers to PPRV and RPV of goats vaccinated with vRVFH ranged from 64 to 2048 and from 64 to 1024, respectively. Although SN titers to PPRV could not be detected in the animals vaccinated with vRVFH on the day of challenge inoculation, all vaccinees were completely protected against PPRV, and no clinical signs (e.g. fever or diarrhea) were exhibited over the following period. In contrast, all the control animals vaccinated with the parental Wyeth strain of VV were febrile ($>39.7\,^{\circ}C$) and suffered from severe PPR within 4 days postchallenge. Three animals died; the rest were euthanized.

Clearly, this vaccine – a VV double recombinant vaccine expressing the *F* and *H* genes of RPV – completely protects goats against PPR, even though no neutralizing antibody to PPRV could be detected before challenge inoculation. Although no anti-PPRV ELISA titers were found in four of the vaccinated animals, and the remaining four had very low titers, all vaccinated goats were equally protected. It has been reported that in cattle administered classic live viral vaccines to RPV, any detectable SN titer is associated with complete protection; this was, however, the first report of protection in the morbillivirus group in the complete absence of SN antibody to the homologous virus. In this regard, we have recently provided evidence that CMI may be the major determinant in protection against morbilliviruses. Cattle vaccinated with subunit antigens (F and H) of RPV expressed in baculovirus produced viral neutralizing antibody but were not protected.

Control of PPR is of great economic importance in countries engaged in large-scale rearing of small ruminants. Until a recombinant vaccine is developed expressing the homologous *F* and *H* genes of PPRV, vRVFH may be used for the control of PPR. Replication of VV is unaffected by antibody to PPRV, and vRVFH can be used to immunize young animals that still have passive (maternal) antibody to PPRV. Also, one can employ a serological test to distinguish vRVFH-vaccinated goats from those exposed to the whole virus, either by vaccination or infection. We have developed such rapid, inexpensive diagnostic kits on the basis of the *N* gene of RPV and PPRV (see Sect. 4).

3.3 A Vaccinia Virus Recombinant Vaccine for VSV

One of the earliest VV recombinants prepared and tested in our laboratory was a vaccine for vesicular stomatitis (VS), a contagious disease of horses, cattle, and pigs characterized by vesicular lesions on the tongue and other areas of the oral mucosa. Interestingly, the virus can be used to infect mice in a model system in which it causes neuropathy and death in 100% of the subjects. A serious cause of economic loss throughout North and South America, this disease is notable for the confusion of diagnosis between VS and foot-and-mouth disease, a pathological epizootic condition with a 100% morbidity rate.

Experimental attenuated and inactivated VSV vaccines have been developed, but

the U.S. Department of Agriculture generally prohibits their use for vaccination because vaccinees cannot be distinguished from naturally infected animals. It is possible to distinguish animals vaccinated with a subunit preparation by serology, however, and this is an essential consideration for epidemiological studies, disease control, and establishment of quarantine programs. Advantages of subunit and live vaccines could theoretically be combined in a VV recombinant expressing specific VSV proteins, and such recombinants were constructed by the methods described for rinderpest.

Of all the antibodies to various proteins of VSV, only those directed to G, the external glycoprotein, have been shown to be protective in mice. When DNA copies of mRNAs for the G- or N- proteins of VSV were linked to a VV promoter and inserted into the genome of VV, the recombinants retained infectivity and synthesized VSV polypeptides. We demonstrated that the polypeptides expressed by these recombinants are similar or identical in size and antigenicity to the natural VSV proteins, and that the G-glycoprotein is transported normally to the cell surface (perhaps important for antigenicity). After intradermal vaccination with live recombinant virus expressing the G-protein (v50), mice produced VSV-neutralizing antibodies. VSV SN titers were detected by day 14 and increased over a 42-day period. Half the mice were given a booster vaccination on day 28, which resulted in a seven- to eightfold increase in SN titers over that obtained with a single vaccination.

Challenge was carried out by intravenous injection of VSV, which produces lethal encephalitis in mice within 6–12 days. For control purposes, a group of mice was vaccinated with vHBs4, a VV recombinant that expresses the hepatitis B virus surface antigen gene. When this group was challenged, 7 of 11 animals died of encephalitis. By contrast, only 1 of 15 mice that received a primary vaccination with v50 died, and none of 16 that received the two vaccinations died.

To further evaluate the immunogenicity of the recombinant virus, cattle were vaccinated intradermally and later given intralingual challenge injections of virulent VSV; the degree of protection correlated directly with the neutralizing antibody produced following vaccination. After vaccination, typical pox lesions appeared within four days. SN titers to VSV were detected on day 7 and reached values of 80–480 by day 29. At that time a second vaccination was given, following which the titers increased several fold. On day 44, the cattle were challenged by intralingual injection of 10^2 and 10^3 PFU of VSV. Preliminary experiments indicated that most unvaccinated cattle challenged in this manner developed vesicular lesions within two days. All controls (unvaccinated cows and cows vaccinated with vHBs4) developed typical vesicular lesions at the 10^2 and 10^3 PFU VSV injection sites. In contrast, only two of six vaccinated cows developed vesicular lesions at the lower challenge dose of VSV. The remaining four cows had no lesions at the 10^2 PFU VSV injection sites, although all animals developed lesions at the 10^3 PFU sites.

Good correlation was observed between antibody titers and protection against challenge with 10^2 PFU of VSV. All animals that were protected had SN antibody titers of 1280 or greater, whereas those that were sensitive had titers of 640 or lower. The degree of protection obtained is particularly noteworthy in view of the severity of the experimental challenge, compared to that of a natural infection.

The VV recombinants protected mice against a VSV challenge that would normally kill all mice within 6 to 12 days. In cattle, two successive vaccinations with the VV recombinant vaccine for VSV provided protection for two-thirds of the animals against a challenge of 100 PFU; this protection was closely correlated with neutralizing antibody titers. The lack of complete protection for all vaccinees may indicate a need for CMI, which is poorly induced by vaccines expressing only the G-protein. It also may be possible to construct recombinants synthesizing considerably more G-glycoprotein, which would provide more effective protection.

3.4 Recombinant Vaccinia Virus Vaccines for SIV

Experimental infection of rhesus macaques with SIV provides a valuable animal model for AIDS vaccine research. Several lines of inquiry recently have brought out the following information:

1. Inactivated whole-virus vaccines have provided limited protective immunity against SIV in macaques challenged with virus propagated in human but not rhesus peripheral blood mononuclear cells.
2. Complete protection from challenge with pathogenic, rhesus-grown SIV was demonstrated reproducibly only in monkeys vaccinated with non-pathogenic (attenuated) *nef*-deleted SIV mutants.

However, whether a live retroviral vaccine could ever meet the safety requirements for human use is highly questionable; this virus integrates into the host genome, induces disease in some animals long after vaccination, and is pathogenic in neonates.

Thus, as an alternative to inactivated and live attenuated classical vaccines, we and others have evaluated the potential of priming rhesus macaques with a live recombinant VV vaccine expressing the glycoproteins of SIV, and then boosting with the same recombinant subunit antigen expressed in mammalian cells, Chinese hamster cells (CHO), or a baculovirus expression vector (see Sect. 4). Protection in these animals was evaluated by intravenous challenge with pathogenic SIV isolates. Although binding antibodies were detected in all animals following immunization with these recombinants, neutralizing antibodies were undetectable one week prior to virus challenge – results that differed from those for macaques vaccinated with whole, inactivated SIV. However, all animals became infected after intravenous inoculation with 1–10 AID_{50} (animal-infectious dose for 50% of subjects) of challenge virus.

There was no protection against infection afforded by any of our recombinant vaccines, even though *in vitro* suppression of virus was demonstrated, and cell-free infectious virus loads in plasma (plasma viremia) of macaques primed and boosted with certain preparations of SIV surface glycoprotein were considerably lower than in unimmunized controls at 2 weeks postchallenge (typically the peak of viremia during acute infection). These studies suggest that immunization with surface glycoprotein may not necessarily provide protective immunity against immunodeficiency virus infection, even though the relationship between reduction in virus load and delay in the onset of disease remains to be evaluated. One protocol did have notable success in heightening the immune response: animals primed with a VV recombinant vaccine and then

boosted with a baculovirus subunit product showed greatly enhanced antibody responses compared to those boosted with the original vaccine.

3.5 Safety and Efficacy of Live Recombinant Vaccines

With the threat of untoward effects always in mind, we have investigated possibilities of further attenuation of our VV recombinant vaccines by the insertion of lymphokine genes like interferon-gamma (IFN-γ) or interleukin-2 (IL-2). This gives us a new approach to enhance safety that should be applicable to other live recombinant vaccines. We constructed fusion proteins of IFN-γ (human and murine species) with various immunogens and demonstrated reduced pathogenicity for immunodeficient (athymic nude) mice with several VV recombinants expressing these proteins. Immunodeficient mice were able to clear the recombinant VV at doses as high as 10^8 PFU, while as few as 10^2 PFU of VV is normally 100% lethal for nude mice. Mixtures of recombinant VVs were always lethal to the mice if one of the recombinant viruses did not express the *IFN-γ* gene, showing that IFN-γ-induced attenuation in VV is only operational in a "cis" fashion.

We have further provided evidence that the antiviral and attenuating activities of IFN-γ have different mechanisms of action. We demonstrated that, unlike antiviral activity, the attenuating activity of IFN-γ is not species specific. Moreover, we have shown attenuating activity of IFN-γ in the absence of any detectable antiviral activity. Although human IFN-γ did not have antiviral activity on murine cells, expression of this cytokine did increase the attenuation of recombinant VVs for athymic mice. It is interesting to note that the anti-inflammatory genes of VV (e.g., its secreted IFN-γ receptor homolog) do not appear to block the attenuating activity of IFN-γ.

The development of an adjuvant system for VV recombinant vaccines may be crucial if the technology is to be considered an effective alternative to classical forms of vaccination, such as inactivated or live attenuated vaccines. We demonstrated that IFN-γ mixed with G-glycoprotein of VSV reproduces the adjuvant effect of complete Freund's adjuvant and further increases the anamnestic response on booster administration. Others demonstrated the adjuvant effects of IL-2.

The use of immunoregulatory genes like *IFN-γ* and *IL-2* as adjuvant genes in multivalent VV recombinant vaccines must be further evaluated. If these lymphokine genes work as adjuvants to augment the immune response, the concept of vaccination will be revolutionized. Such natural products could eliminate the need for harsher adjuvants (e.g., Freund's) and thus avoid the untoward effects presently observed. The human *IFN-γ* gene could be incorporated into VV vectors for human pathogens, and similar vectors could be constructed for other domestic species.

Another method to increase the safety and efficacy of recombinant VVs is to inactivate or delete virulence genes. The NYVAC VV was constructed by deleting 18 *VV* genes from the extremities of the virus in which the virulence and species-specificity genes are encoded. This virus is similar to MVA, causing an aborted infection in mammalian cells but replicating in chicken embryo cells. These viruses generally require multiple boosts to generate protective immunity; thus, we have been exploring the effect of deleting VV virulence genes individually. VV is one of many

viruses with genes that code for specific proteins to suppress host immunity. These immunomodulating genes are usually not essential for virus growth *in vitro*. They include homologs of cytokine receptors, complement control proteins, and serine protease inhibitors (serpins). In particular, VV contains a gene (B8R) that codes for a secreted protein with sequence similarity to the extracellular domain of the IFN-γ receptor. The B8R protein neutralizes the antiviral activities of IFN-γ from several species. Serpins play important roles in the regulation of immune and inflammatory responses as well as cell death. The B13R (SPI-2) gene codes for a serpin homolog that interferes with host inflammatory responses by inhibiting the proteolytic activity of caspase-1, also known as IL-1β converting enzyme, and granzyme B. Similarly, the (SPI-1) B22R gene plays a role in reducing the host's immune responses to the virus. We hypothesized that deleting these immunomodulating genes would increase the efficacy and safety of recombinant VVs. While deletion of these genes had no effect on virus replication *in vitro*, recombinant VVs lacking these genes were attenuated for mice. There was a significant decrease in weight loss and mortality in normal mice, and immunodeficient nude mice survived significantly longer than controls inoculated with parental virus. Finally, the deletion of these genes did not reduce humoral immune responses. Mice and rats vaccinated with the recombinant VVs showed identical humoral responses to both homologous and heterologous genes expressed by VV.

3.6
Potential Recombinant Vaccines for HIV

Several laboratories are investigating VV recombinants as vaccines for human immunodeficiency virus (HIV) infection. It has been shown that the HIV antigens expressed by some of these recombinants are correctly processed and transported to the appropriate cellular compartments. Moreover, experimental animals as well as human volunteers that were vaccinated were shown to develop detectable CMI to the expressed HIV proteins. There is considerable interest and some optimism that an effective vaccine might be prepared using VV as a vector.

Innovative solutions to the safety problems occasioned by putting such a vaccine into general use are gaining attention, especially following the report of a disseminated VV infection caused by smallpox vaccination of an army recruit with subclinical HIV infection. It has been demonstrated that VV is attenuated by insertional inactivation of its *TK* gene. Also, the expression of IL-2 and murine IFN-γ has prevented disseminated VV infection in immunodeficient nude mice.

4
Baculovirus Expression Vectors and Rapid Diagnostic Kits

The VV recombinant vaccines prepared for rinderpest, PPR, VS, and SIV, all lend themselves to employment of a new rapid diagnostic technique that our laboratory has prepared in kit form. The baculovirus expression vectors used in our laboratory give us the capacity to produce large quantities of different virus proteins that may be used as coating antigens for ELISAs. When an internal protein gene such as the *N* gene of RPV or VSV, or the gag gene of SIV, is incorporated into the genome of this insect virus strain before infection of a larval host, the virus polyhedrin promoter drives a very

high level of expression of recombinant protein (up to 67% of the weight of the larva). The protein from one infected and homogenized larva (0.2–0.3 g) provides antigen sufficient for coating 200 standard 96-well ELISA plates, which can be used to diagnose up to 10 000 serum samples in duplicate. Purification of the N or gag protein appears to be unnecessary; there was no interference or loss of sensitivity using the crude larval lysate for coating ELISA plates.

Used in conjunction with a recombinant vaccine incorporating a gene for a major immunogen of the disease agent, these ELISAs allow distinction of vaccinated animals from those that have been naturally infected. Vaccination with the recombinant produces antibody to the incorporated gene's product only, while natural infection brings about responses to many different antigens. This test differentiates animals showing responses to a variety of proteins (naturally infected by the disease agent) from those that respond only to the vaccine's foreign gene product (vaccinees).

We have also introduced a novel approach for the production of monoclonal antibodies to one specific protein of a virus or other agent consisting of several proteins, without the use of purified antigen in either the immunization or screening phase of the procedure. This approach utilizes a VV recombinant expressing the gene of the target protein for the immunization of mice and the whole virus for screening of the hybridoma to identify the desired monoclonal antibodies. This system has been effective in producing monoclonal antibodies to rare antigens like Alzheimer's protein, or to those – the VSV nucleocapsid (N) protein, for example – that cannot be easily screened for biological activities such as hemagglutination or neutralization.

5 Advantages of Vaccinia Virus Recombinants

Experience with mass production, storage, and administration of smallpox vaccine suggests that VV or related poxvirus recombinants could be the basis for veterinary and human vaccines offering advantages over current preparations. Lyophilized VV is heat stable and can be effectively administered by a variety of methods. During the global eradication of smallpox, scarification or jet gun administration was used to vaccinate millions of people. We have vaccinated animals by intradermal inoculation and scarification, and we plan to investigate the effectiveness of oral administration for wildlife and cattle.

It is possible to make a polyvalent vaccine using VV as the vector, by expressing several genes that represent a number of unrelated agents. While the manipulations for including several genes are increasingly difficult with each addition, new methods are being developed rapidly. The possibility of developing a polyvalent vaccine, with a single VV recombinant expressing a number of heterologous genes, is especially important for nomadic regions of Africa and Asia. Theoretically, one stock of VV could carry genes from most of the important livestock diseases in a region, and one inoculation could vaccinate an animal against half-a-dozen or more diseases.

The VV recombinant vaccine contains very few antigens in common with disease agents, and so we have found it possible to develop diagnostic kits for rinderpest, vesicular stomatitis, and simian AIDS that can distinguish vaccinated animals from those exposed to the whole agent either by infection or vaccination. Currently, we are expanding this technology to provide

rapid diagnosis for a variety of livestock diseases.

We recognize the potential safety problems with widespread use of VV as a vector for different vaccines. However, the strains used for vaccine construction were used worldwide without serious problems in the successful eradication of smallpox. Further, it has been demonstrated that insertional inactivation of the *TK* gene attenuates the virus. In constructing the first rinderpest double recombinant vaccine (vRVFH), the *TK* gene of VV was inactivated by insertion of the RPV *H* gene; insertional inactivation of the VV HA region by incorporating the *F* gene of RPV has led to further attenuation of the recombinant virus. The absence of detectable pock lesions at the site of vaccination by the double recombinant is an indication of its greater attenuation, even though it is still completely protective. Moreover, vRVFH is highly attenuated and is apathogenic for both athymic nude mice and SIV-infected rhesus macaques.

To improve efficacy, we constructed a second generation VV double recombinant vaccine for rinderpest (v2RVFH) that expresses both the *F* and *H* genes of RPV under strong synthetic VV promoters at the TK site. v2RVFH-infected cells express higher levels of the F and H glycoproteins than vRVFH and show extensive syncytium formation.

It is important that safety considerations be thoroughly addressed before live recombinant viruses are introduced into the environment. The rapidly expanding epidemic of HIV, particularly in Africa, demands that live vaccines do not pose a threat to indigenous populations. The safety of VV recombinant vaccines has been confirmed by the absence of transmission of VV from vaccinated to contact animals. No pock lesions or antibody to VV, as measured by SN and plaque reduction assays, could be demonstrated in control animals housed in contact with cattle vaccinated with vRVFH or v2RVFH. We believe that these outstanding safety features of these vaccines make them suitable for field use. We believe also that these vaccines are only the first to bring the benefits of modern molecular biology and biotechnology to disease control. As knowledge and expertise in these fields expand, recombinant vaccines will be constructed for many of the more stubborn afflictions of human beings and animals, providing creative solutions to disease problems, old and new.

Bibliography 329

Keywords

DNA Polymerase
Enzymes that make DNA using DNA as a template. There are several different DNA polymerases in most cells and they have somewhat different properties with respect to their error rate and ability to use noncanonical templates (examples of noncanonical templates are ribonucleotides in DNA, 8-oxy-Guanine and other chemical lesions in bases or backbone).

Evolution
Change with time or in the series (generations) of a lineage in the same direction as the flow of time.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Edited by Robert A. Meyers.
Copyright © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim.
ISBN: 3-527-30547-5

Genetics
Mechanisms by which information is transferred between generations. The term ''genetics'' has its origins in biology and ''generations'' refers to progeny cells, viruses, or multicellular organisms. The genetic properties of descent with modification are present in other contexts, such as computer programs known as *genetic algorithms*.

Genetic Evolution
Change in the hereditary information with time, especially if transferred to subsequent generations.

Genetic Algorithms
A class of computer algorithms with certain characteristics. GAs consist of bit strings that give rise to progeny bit strings. Some progeny are identical to the parent and some are different. The population of bit strings compete with each other for survival and reproduction according to selection criteria mediated by the program environment.

Genetic Change
Alterations of hereditary information. Typically – but not always – genetic change occurs concomitantly with replication of the organism.

Mutation
A genetic change in which preexisting hereditary information is not transferred to a new context.

Recombination
A genetic change in which preexisting hereditary information is transferred to a new context.

Recombination, Homologous, Legitimate, Generalized
Recombination in which the similarity of two sequences is a requisite for their ability to recombine. To a first approximation, the homologous recombination depends on the similarity not on the specific sequence.

Stress
A differentiated physiological state in response to nonoptimality perceived by the organism. SOS in response to the stress of DNA damage was the first characterized stress response. Others include responses to osmotic stress, the presence of unfolded proteins in the cytoplasm, and various nutritional starvations. Various stress responses tend to partially overlap.

Intelligence
Tools and mechanisms for receiving information from the environment and adjusting responses; problem solving – arguments over types and measures of intelligence abound.

Genetic Intelligence
Hereditary information responsible for the mechanisms that generate genetic change.

Environment
Systems are often defined as having an ''inside'' and an ''outside.'' The environment of a system consists of anything ''outside.'' The outside of an organism is defined by its skin; the outside of a cell is defined by its membrane. The outside of a chromosome is the cellular milieu and the outside of a DNA base is all of the above as well as its sequence context.

Random Mutation
A mutation that is no more likely to occur in environments that select for it than in environments that do not. In the context of genetics and mutation, ''random'' does not mean that every possible change is equally likely to occur. Even in the narrow context of point mutations, there are inherent biases in all examined systems.

Adaptive, Directed, or Cairnsian Mutation
A mutation that is more likely to occur in circumstances in which the mutation is advantageous, that is, nonrandom mutation. ''Strong'' adaptive mutations are those that do not appear to be generalized stress-responses and that are highly specific.

Lethal Environmental Selection
Environments that kill unfit organisms and kill them quickly, that is, before they have the ability to mount a stress response that might prolong their agony, or, allow them to consider ways to escape the problematic situation of the selection.

Nonlethal Environmental Selection
Environments that prevent, stop, or slow the growth of unfit organisms without killing them. These situations provide the organism with problems that it has the opportunity to solve over time. Often a stress response may be involved in an organism's attempt to solve the problem of nonlethal or slowly lethal selections.

Fixation of Genetic Change in an Individual Organism
An irrevocable commitment that a new allele will be inherited by progeny.

The purpose of this article is fourfold: (1) To frame the intellectual context of ''adaptive'', ''directed'', or ''Cairnsian'' mutation. This area of research is – and will likely remain – controversial. (2) To review the points to be considered when critically reading in the field; (3) to consider the question of how mechanisms for an ''intelligent'' generation of diversity could evolve and, in this context; (4) to suggest connections between the fields of genetic algorithms in computer science and those of biological evolution proper (carbon – rather than silicon – based life forms).

1 Historical and Intellectual Context

Lamarckian interpretations persisted longer in microbiology than in other domains of biology. In part, this was due to the plethora of traits and organisms being observed and interpreted with a limited set of conceptual tools. Different traits and mechanisms turned out to be involved, which are now realized to include at least five classes: operon induction, mutation, transposition, chromosome rearrangement, especially duplication, and phase variation such as those mediated by the site-specific recombination systems, lysogenic transformations, and other extragenic elements. The difficulty in inferring genotype from phenotype for these quite different mechanisms contributed to the confusion. The polemic reached high levels and resolution of the controversy – albeit temporary – had a major effect on the development of modern molecular biology.

Luria and Delbruck made an enormous dent in the debate with their classic experiments that were designed to address one aspect of the Generation of Diversity (GOD) question: ''Do mutations arise in response to the conditions that select for them or are mutagenic variants preexisting in the population but unseen in the absence of selection?'' The Luria and Delbruck experiments are of the following form. A number of replica liquid cultures were each inoculated with a small number of bacteria. ''Small'' means few enough cells such that no T1 phage–resistant cells are present to begin with. The cultures were then allowed to grow to saturation and the number of mutant cells in a sample was determined. Mutant cells were enumerated by spreading samples of the cultures onto petri plates that had been seeded with several million T1 phages. Only cells resistant to T1 phage could give rise to colonies. The question is, ''Did the T1-resistant phage exist in the liquid culture before there existed any selection for them or was the resistance to T1 phage induced by the selective condition itself?'' In the former case, the role of the environment is restricted to selection for preexisting mutants; in the latter case, the environment also plays a role in generating the mutants it subsequently selects. Luria and Delbruck made the quantitative argument that resistance to T1 phage arose in the absence of selection. The argument was based on two elements: (1) If each cell has a given probability (e.g. one in a million) of mutating in response to the challenge, when a large number (typically one hundred million cells present in one-tenth of a milliliter of a saturated overnight culture of the bacteria) of bacteria are spread onto a plate, the number of resistant mutants found on each plate should represent a Poisson distribution around the arithmetic average (e.g. 100 in the numerical example given). (2) On the other hand, suppose that mutants arise during the nonselective overnight growth at the same rate of one in a million. Mutant cells, arising before the culture is saturated, will give rise to mutant progeny, and cultures will therefore contain clones of mutants rather than single mutants. Luria and Delbruck's model in which mutants arise independently of their subsequent selection predicted a wide (i.e. wider than Poisson distribution) variation in the number of mutants in a series of cultures. The quantitative analysis of Luria and Delbruck assumes that mutation occurs at a constant probability per cell division.

The respreading experiments of Newcomb, as well as the replica plating of

Lederberg and Lederberg were both advanced as confirmation of the conclusion reached by Luria and Delbruck. Replica plating used sib-selection to achieve a direct demonstration that clones of resistant mutants (to the drug streptomycin) existed prior to and independent of selection.

The formulation of Luria and Delbruck states that mutation is a function of the number of cell generations with a fixed probability of mutation at each generation. This way of thinking about mutation resonated well with a molecular mechanism that involved misinsertion of bases during normal replication. It also fits with a model of gradualistic evolution that occurs via the misinsertion of bases during normal replication. Molecular clocks based on a constant rate of random-base substitution made tidy icing on the hostess twinkee of the neo-Darwinian synthesis.

Many interpretations of these three classic experiments erroneously conflate the elements of clonality with the time that a mutant arises. The incorrect assumption being that if mutants arise independent of the selection, then mutants will give rise to clones before the assay. On the other hand, if mutants arise after the selection is imposed, then each mutation event will result in a separate enumerable colony. In the former case, enumerating the number of mutants is an indirect measure of the mutation rate; in the latter case, the rate of mutation is given simply by counting the number of mutant cells and dividing it by the total number of cells tested.

A shrill stridency associated with the view that all mutations arise without regard to their subsequent selection is well illustrated by Monod in his 1970 book *Chance and Necessity*:

> In modern biological research, some of the most outstanding work, both as to methodology and to significance, bears upon the area known as molecular genetics (Benzer, Yanofsky, Brenner and Crick). In particular, this work has made it possible to analyze the different types of discrete accidental alterations a DNA sequence may suffer. Various mutations have been identified as due to
>
> 1. The substitution of a single pair of nucleotides for another pair;
> 2. The deletion or addition of one or several pairs of nucleotides; and
> 3. Various types of ''scrambling'' of the genetic text by inversion, duplication, displacement, or fusion of more or less extended segments.
>
> We call these events accidental; we say that they are random occurrences. And since they constitute the *only* possible source of modifications in the genetic text, itself the *sole* repository of the organism's hereditary structures, it necessarily follows that chance *alone* is at the source of every innovation, of all creation in the biosphere. Pure chance, absolutely free but blind, at the very root of the stupendous edifice of evolution: this central concept of modern biology is no longer one among other possible or even conceivable hypotheses. It is today the *sole* conceivable hypothesis, the only one that squares with observed and tested fact. And nothing warrants the supposition – or the hope – that on this score our position is likely ever to be revised (pp. 112–113 Italics are in the original)

Monod goes on to say:

> There is no scientific concept, in any of the sciences, more destructive of anthropocentrism than this one, and no other so rouses an instinctive protest from the intensely telonomic creatures that we are.

Monod is correct in the consequences of his last statement but he is wrong in his dogmatic emphasis on the impossibility of contradiction. The authors of the present article believe that ''modern biological research'' including molecular genetics does not preclude the opportunity for

theory and experiment in which mind and nature are not *a priori* at odds.

2
Cairns and Precursors

In 1988, a paper that continues to stimulate intense work and controversy among molecular biologists, geneticists, evolutionists, and even philosophers was published. The results suggest that some mutations arise more frequently when they are being selected for, in apparent contradiction to the idea that mutations arise without regard for their utility. The role of the environment in selecting among preexisting variants is not challenged by these approaches; rather the environment is endowed with roles in generating the variation upon which selection acts.

An essential aspect of protocols that search for adaptive mutagenesis is the use of nonlethal selection, for example, lactose prototrophy. Luria and Delbruck's selection was for resistance to phage T1. A cell becomes resistant to T1 by mutating its gene for the phage receptor. *Escherichia coli* has about 200 phage receptors on its surface. Even if a bacterium was ''smart'' enough to immediately mutate the gene for the receptor as soon as it ''saw'' itself threatened by phage, it would still be dead by virtue of an already existing protein. Phage receptors are passed along with the wall at cell division. Vulnerability to phage lysis continues for several generations even after a mutation prevents the gene from encoding a new phage receptor. For this reason, the experimental protocol of phage resistance was only capable of documenting mutations that had occurred several generations before selection was applied. This protocol was only able to address the point that mutants can and do arise in the absence of selection. It was never capable of addressing the question of whether selection can induce mutation. A similar limitation is inherent in the Lederberg and Lederberg experiments because of the nature of the streptomycin-resistance assay. In order for the resistance phenotype to be expressed in a cell, sensitive ribosomes must be diluted out by growth after the mutation has occurred.

Cairn's 1988 paper and the questions raised by it were not without precursors. Some of these precursors will be mentioned with an eye to what was different in the formulation of Cairns.

Max Delbruck may have been the first to recognize the limitations that could be rigorously inferred from his paper with Luria. In the 1946 Cold Spring Harbor Symposium (published in 1947), Delbruck says ''... In view of our ignorance of the causes and mechanisms of mutations, one should keep in mind the possible occurrence of specifically adaptive mutations...or should exclude their occurrence in a variety of specific cases.''

The conclusion that mutation occurs as a consequence of errors arising during replication is incomplete on several counts. Frances Ryan, in the late 1950s and early 1960s, demonstrated that prototrophic revertants of *E. coli* histidine auxotrophs could accumulate while the cells were not growing. Meiosis is another case in which genetic change is massively increased during a single replicative generation. Interallelic recombination per cell division in yeast meiosis is increased between 10^3 and 10^4 when compared to the mitotic recombination rate between the same alleles. Radiation and chemical stimulation of genetic change certainly make it clear that the environment can

create the lesions in DNA, which are subsequently processed to fix mutations. Premutagenic lesions of many sorts in many sorts of cells are induced by chemicals or radiation in nongrowing cells and require subsequent growth for enumeration. That they may also require growth for their fixation has the makings for adaptive mutagenesis.

Mutagenic mechanisms can alter replication fidelity even at nonlesioned sites. One of the products of the SOS DNA damage-repair response regulon acts as a negative regulator of the $5' > 3'$ exonuclease of DNA polymerase. When the $5' > 3'$ exonuclease functions, the polymerase is between 10^3 and 10^4 times more accurate. This nuclease activity is known as *editing* or *proofreading* because it preferentially excises incorrectly, that is, non-Watson–Crick-paired terminal nucleotides. During the SOS response, overall DNA replication is decreased in fidelity. The qualitative nature of genetic change is also altered during the SOS response, that is, some types of mutations arise relatively more frequently than others. Nontargeted mutagenesis during the SOS response was the subject of considerable polemic around ideas of ''inducible evolution'' that were the immediate precursors of controversy around specifically adaptive mutation.

Barbara McClintock considered genomic change to be an important mechanism for both differentiation and evolution. These ideas were formed before the rise of the operon theory, partly in the context of somatic adaptation. McClintock remained concerned with the possibilities and properties of adaptive genomic change. In her 1983 Nobel prize lecture, she said ''A goal for the future would be to determine the extent of knowledge the cell has of itself and how it utilizes this knowledge in a ''thoughtful'' manner when challenged.'' James Shapiro, in the discussion of his 1984 paper, pointed out that the Luria and Delbruck, Newcomb and Lederberg and Lederberg experiments involved immediately lethal selection and could only detect mutants that had originated in the absence of selection. He ended this important paper with the statement: ''Indeed, now that we know about mobile genetic elements, inducible mutator systems and multiple biochemical activities that reorganize DNA molecules, the most pertinent questions in studies of hereditary change must be questions of control and regulation.''

The special contribution of Cairns and colleagues is that the distinction between generalized stress responses and ''thoughtful'' reactions of the organism was for the first time explicitly incorporated into experimental protocols. The adequacy of the methods used has been the subject of much criticism and refinement, but the field of adaptive mutation, while not getting calmer, has – on average – been reaching higher intellectual levels ever since.

If Ryan had included nonselected genes in his experiments, adaptive mutation as presently discussed would have been discovered before 1960. Shapiro's 1984 paper does not include nonselected genes; when the experimental design was extended to include tests inherent in Cairns et al. 1988, the results of Mittler and Lensky indicated a more generalized stress response. On the other hand, more recent work by Shapiro in 1994 indicated that the sequence of mutations was different depending on whether the mutations arose under selective or nonselective conditions.

3
Critical Reading of the Adaptive Mutation Literature

This field of science is likely to remain populated by mixed herds of sheep, goats, and unicorns. To aid critical reading, some hints and questions to keep in mind while examining the literature will be enumerated.

1. If mutants occur prior to selection but they grow slowly, then the appearance of Luria–Delbruck ''jackpots'' will be suppressed. Slow growers also may come up later under selection giving a false clue that the mutation arose after the selection was imposed.
2. Always consider the possibility of, and the amount of, growth under conditions where growth is not supposed to happen. For example, in cases where a lactose negative cell is asked to mutate such that it can grow on medium with lactose as the sole carbon source, might there be a smidgen of glucose in the lactose medium? Even if cell numbers do not increase, there may be cell turnover via cannibalism. Is there a chance for cross-feeding between cell types that are present, or could cross-feeding arise under the selective conditions? In the absence of growth, are other processes such as phage induction, conjugation, or meiosis still possible and how might they contribute to the results observed?
3. Is the type of change occurring under selection the same type that occurs during nonselective growth? If the spectrum of mutations recovered is different, then the evidence is much stronger that a different mechanism is operating under one condition than another. One must be on the lookout for unexpected sources of selection and for reconstructions to address them.
4. Are the genetic dependencies of mutation the same under selective and nonselective conditions? Different genetic dependencies are bona fide evidence of different pathways, although one must always be cautious of the ''kicking 'em when they're down'' syndrome, that is, some mutations may result in a cell that is weaker and not able to grow well under challenged conditions.
5. Is the selection completely lethal or nonlethal? If nonlethal, how much of a stress is it? Is there a general stress response pathway – such as SOS, carbon starvation (cAMP), or amino acid starvation (stringent response), which could be invoked under the experimental conditions? In what ways does the experimental design distinguish between known stress responses and keep in mind the possibility of new ones?
6. What is the evidence for specificity? Are there control genes that are not under selection but whose mutation or recombination rate can be measured? What is the relation of control genes and their assays to the experimental ones? The best experimental designs have symmetry, that is, selections for one or the other gene with measurement of the rate of change in both. Are the results reported as both absolute quantities of change (e.g. mutation rate per cell) and as a ratio of different types of change? Is the evidence for ''adaptive'' mutation based only on the time of mutants arising or is it also based on ratios and the spectrum of mutation? For example, it has been noted that some replicons give a higher mutation rate under some physiological conditions. Again, this speaks about the consideration of experimental design and the necessity to be both rigorous and open-minded in considering both

what the results "make you believe" and what they "allow you to believe."

4 Mechanisms Proposed for Adaptive Mutagenesis

Many mechanisms have been proposed for the apparently Lamarckian inheritance that occurs under some regimes of nonlethal selection. In this section, several such mechanisms will be mentioned. Some of the following classifications are orthogonals. This list should be considered rather like a deck of cards of ideas, which the thinker can draw upon in interpreting results and controversies.

1. Mechanisms in which the mutation rate is increased over a small portion (say 1%) of the genome in each cell such that in a population all regions will be highly mutagenized. This category was proposed by Barry Hall who subsequently provided counterevidence to the corollary that sequence changes should be clustered.
2. Mechanisms in which the global generation of mutations is increased in response to properly perceived stress (PPS). This class of events is to generalize most directly from SOS-induced mutagenesis and from the facts of meiosis, that is, that there are physiological circumstances of PPS in which the overall mutation rate is altered. Slightly more focused and specific are models in which the mutation rate for a subset of the total genes in the organism is altered as a function of some condition. Candidate mechanisms to focus mutation onto a subset of genes include genes and processes that regulate operon and regulon expression. The induction of specialized DNA polymerases and/or the inhibition of polymerase editing can enter via this route.
3. Mechanisms that invoke error-prone DNA synthesis, either over small regions of the genome such as gaps created during conditions of starvation or over an entire round of replication. Specialized polymerases can contribute to region, lesion, or time-restricted mutation.
4. Homologous recombination is part of several proposals. Rosenberg has reviewed recombination models of several sorts including those in which error-prone synthesis is concomitant with recombination and others in which the degree of sequence similarity required for homologous recombination is varied under conditions of properly perceived stress.
5. Most intriguing are mechanisms in which the generation of mutation and its fixation are separated. This separation is accomplished by making fixation dependent on growth at the critical moment. This class of mechanisms was first suggested in the seminal 1988 article by Cairns et al. They proposed a specific mechanism in which error-prone transcription occasionally results in a wild-type transcript being produced from a mutant locus. This mRNA will allow the cell to grow momentarily. The model further proposes that the change in physiology attendant to momentary growth results in a burst of reverse transcriptase activity that acts on mRNA resulting in DNA that homologously recombines with the chromosomal locus to fix the mutation.

FW Stahl proposed a mechanism in which gaps in the DNA arise during starvation and are filled in by error-prone

DNA synthesis. New DNA synthesis is normally undermethylated and subject to mismatch correction in favor of the old chain. However, if the cell starts to grow – for example, owing to error-prone synthesis resulting in a wild-type allele – then the mismatch will be resolved by replication, and the mutation will be fixed in one of the progeny cells. Shapiro and colleagues have proposed and presented supporting evidence that gene fusions mediated by phage mu are modified by local transcription and replication.

Models of the type proposed by Cairns and by Stahl have often been discounted on the basis of evidence of double mutants among the products of single selections. This finding is taken to be evidence of the cells having been through a general state of high mutation rate spread throughout the genome. Although consistent with a temporary state of generalized high mutation, the presence of double mutants among the products of selection for single mutants is not definitive evidence. It has not been generally appreciated that the same result would be obtained if reversible intermediates were present at several places around the genome at the same time. If the integrated effect of reversible intermediates is positive for cell replication, then they will all be rescued via replication in a sort of ''group hitchhiking.''

5 How Might Genetic Intelligence Have Evolved?

The generation of genetic variation is, in large part, a function of the genes and physiology of DNA metabolism. Genes responsible for the generation of particular alleles will tend to be coinherited with the alleles that they played a role in generating. The components exist for feedback between the generators of genetic diversity and the environment that selects among variants. The utilization of this capability to generate, among the range of all possible variations that subset that is ''anticipated'' to be of use, is admittedly a radical proposition but we contend that it should be taken seriously. Figure 1 illustrates the conventional view of evolution. In this simple view, the sole act of the environment is to select among variants; there is no role for the

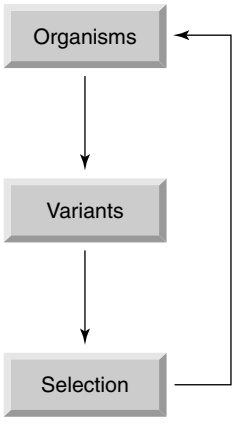

Fig. 1 A conventional view of evolution. The environment functions only at the selection step.

environment to play in the generation of diversity. In Fig. 2, a more complex and realistic view of evolution is shown. The environment acts both on the generation of variation and as a selective agent among variants.

The action of the environment on the generation of variation takes several forms and goes via several routes. In direct action on DNA, radiation or chemicals alter the chemistry leading to a change in base sequence. These agents can also act less directly by modifying proteins involved in DNA metabolism. This is the route by which topoisomerase inhibitors or agents that alter nucleotide pools can promote mutation and recombination. Even the most direct action of the outside environment on DNA requires processing by DNA repair and replication proteins in order to become fixed as a mutation. The ''environment'' of a DNA sequence means the cell's internal milieu and state as well as that which is outside an organism's skin or membrane. Even its sequence context is properly considered part of the ''environment'' of a particular base.

At no stage of evolution could the generation of diversity ever be purely ''random,'' if by ''random'' it is meant that every sort of change is equally probable. For the initial discussion, let us limit the case to substitution mutations in which the polymerase allows the pairing and ligation of a non-Watson–Crick base pair, and uses that mispair as the primer for further extension. Until another round of replication, the mutation is not fixed; it remains vulnerable to mismatch correction. A purely random model for the generation of missense mutations would suppose that all the substitutions are equally common and that the rate of substitution is invariant. Both these points are not accurate statements. The rate of each possible substitution mutation is different, both because the polymerase has a different propensity to make each sort of mistake and because the mismatch correction system has different affinities for each of the possible mismatched base pairs. The rate of substitution mutation is strongly affected by the nucleotide pools; such pools are altered with cell physiology. The proofreading of polymerase is specifically inhibited by the SOS-induced gene *umu*D. Transcriptional focusing could allow regulation of genetic change to be as tightly coupled to the organism's perception of its environment, as is gene expression.

Much of what is inherited is not due to a direct effect on survival; rather it is the product of neutral selection. The information mediated by perception that modulates physiology may or may not be congruent with that which alters genetic metabolism. In Fig. 2, what is the relationship of information flowing through arrows 3 and 4, and what modulates that relationship via physiology and evolution? We are not claiming that evolution moves inexorably toward anticipatory mutation. We simply point out that the tools and feedback mechanisms exist such that life *could* evolve the ability to focus the generation of variation where an evolved mechanism ''guesses'' or ''anticipates.'' Mutation rate is sometimes portrayed as a compromise of fidelity, economy, and the occasional need to generate variation. Differential variation with respect to genes and time offers a way out of compromise, particularly if sensitive to the environment.

Rapid bacterial evolution to antibiotic resistance and clonal evolution in oncogenesis both involve concerted genetic changes that may include aspects of selection-promoted mutation. The immune system of mammals has several aspects of focused

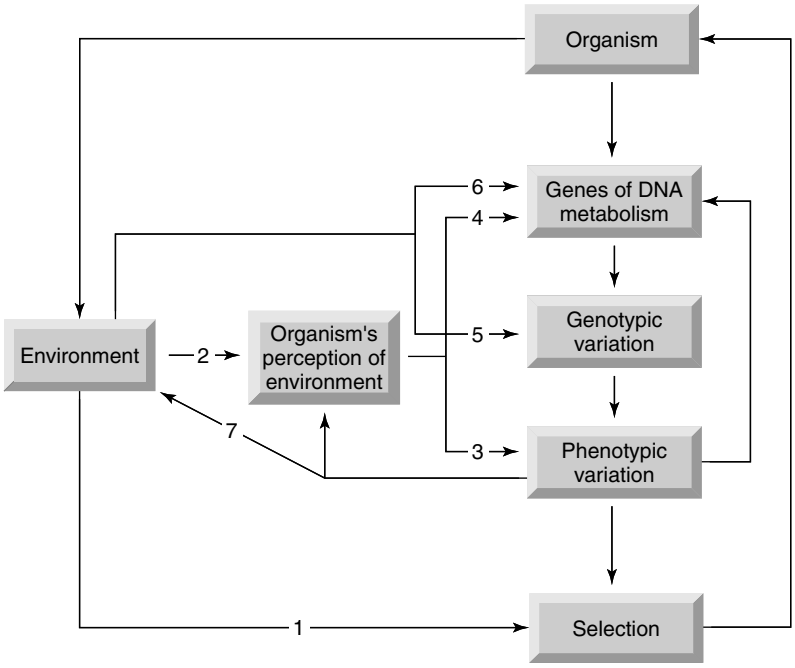

Fig. 2 A more complete view of evolution. The environment functions at three stages. (1) The environment is the proximate agent of selection. (2) The environment is perceived by the organism. (3) Organisms use their perception of the environment to modify their physiology, as in operon induction. (4) Organisms use their perception of the environment to modify their genetic metabolism, as in the SOS and p53 pathways. (5) The environment directly impinges on the DNA directly via such agents as radiation and chemical mutagens. (6) The environment can interact indirectly on DNA via the genes of DNA metabolism, as in topoisomerase inhibitors in chemotherapy. (7) The organism modifies environmental interaction with the genome as in metabolic activation, or, detoxification.

and adaptive mutation, including somatic mutagenesis at the VDJ junction and receptor editing. Study of these processes implies a further feedback loop.

6 Genetic Algorithms

Genetic algorithms are computer codes inspired by analogies to biology and the chromosome, and capable of evolving. In this section, the means of generating diversity in genetic algorithms and the possibility of using genetic algorithms to evolve a pseudogenetic intelligence are discussed. Computer algorithms are not constrained to mimic the biological systems that inspired them. However, in terms of mechanisms to generate diversity, there is a richness of carbon-based genetics, which has not yet found its way into silicon.

The evolution of a computer began by constructing analogies for natural components. The binary code sequence of 0s and 1s is analogous to the nucleotide sequences of G, A, T, and C. The

next analogy involves natural selection. Selection is typically taken to be a process whereby individuals of greater fitness are more likely to survive and propagate. The fitness evaluation of genetic algorithms is not directly related to the generation of diversity and will not be discussed here further.

The basic outline of a genetic algorithm is as follows:

1. Create a population of chromosomes
2. Evaluate the fitness of all chromosomes
3. Select parents from among fitter chromosomes
4. Produce offspring from parents while employing diversity generating operators
5. Apply selective pressure to remove less fit chromosomes
6. Return to step 2.

Each of these steps requires variables that may be chosen arbitrarily. In particular, the variable operators in step 4 could be developed to give genetic algorithms greater potential for generating diversity in manners similar to natural systems.

Genetic algorithms utilize bit strings analogous to chromosomes. The length of the chromosome is arbitrary for any given algorithm. The figure below is an example of a binary chromosome of length 40.

1010010010000101111001100101010101010101

The reproductive aspect of genetic algorithms varies widely in method, but there are some common features that are essential to any genetic algorithm. The most important of these features is the generation of diversity among the offspring of the parent chromosomes.

It is the generation of diversity and the subsequent selection for the fittest individuals that allows genetic algorithms to display evolutionary behavior. Natural systems have evolved a wide variety of techniques for altering the arrangement of their chromosomes and analogous techniques can be instituted in genetic algorithms. Doing so might have the double advantage of allowing genetic algorithms to adapt to more complex situations while also providing a tool for observing evolutionary behavior of the algorithm.

The simplest means of generating diversity in a genetic algorithm is random mutation concomitant with replication. A bit flip (from 0 to 1 or *vice versa*) occurs at an identical and fixed probability for each position at each replication. This is analogous to random-base substitutions in the nucleotide sequence of an organism. The probability with which mutation occurs is set by the algorithm design. We doubt that random mutations alone can provide the optimal generation of diversity for genetic algorithms.

Insertion and deletion of single bases are simple extensions of base substitutions. Polymerase replication errors are most commonly cited as the cause for these mutations in natural systems. They are manifested in a genetic algorithm in the same manner as random bit flips, at some given probability in each reproduced chromosome. Below are examples from both nucleotide and binary sequences.

Random Mutation

It is important to note that these three mutations do not always occur at the same rate at every location of a natural chromosome. They frequently depend upon sequence context. For example, inserted bases resulting from a looping-out error on a newly synthesized DNA strand occur more often in stretches of repeated bases (i.e. GACCT**AAAAA**TCGAT). Therefore, the genetic algorithm that seeks to model this phenomenon must vary the probability of the mutation occurring in specific sequence environments. These types of mutations can provide diversity from parent to offspring but do not allow any exchange of information between existing parents. For that to occur, mating, and some form of genetic recombination must take place.

Genetic recombination is a common occurrence in natural systems and forms the basis of sexual reproduction. The ability to exchange and reorder DNA is fundamental to the evolution of sexual organisms; it is also important to genetic algorithms. Currently, genetic algorithms recombine in very limited, but powerful, ways. The figure illustrates a common form of recombination used. In this technique, the two parent chromosomes are first passed through a crossover probability function. This determines the probability that the two parents will recombine. Once passed, a point on the chromosome is randomly chosen (in this case the tenth position) and the codes are swapped from parent to parent.

Parent 1	11111111111111111111111111111111111111
Parent 2	00000000000000000000000000000000000000

Offspring 2	00000000001111111111111111111111111111

The power of this procedure derives from the fact that it allows the exchange of large blocks of code; blocks that could contain useful groups of code. Studies have shown that blocks of code that tend to increase the fitness of the chromosome increase their frequency in the population over many generations. These blocks

have been termed schemata and they are roughly analogous to genes. Other extensions of this procedure are sometimes used, typically allowing for more than one crossover point. However, despite its power, this technique is not an accurate representation of natural systems. Biological organisms do not experience completely random recombinations. Instead, there are a number of regulatory conditions that affect the probabilities of where and when recombination occurs. In homologous (= generalized = legitimate) recombination, such as that which occurs during meiosis, recombination is dependent on similarity between two sequences. The exact degree of similarity required is itself a genetically regulated parameter. Similarity matching in genetic algorithms would require an operator that compares lengths and similarity, and if satisfied, recombines after an appropriate probability function. For example, the two parent chromosomes in the figure below will only recombine if there is similarity in 9 bits out of 10, and then only 50% of the time.

Parent 1	**10101001***00111011010***100101011010010101011**
Parent 2	00010110*00101011011*1111001101011010111100
Offspring 1	**10101001001110**1101111100110101101011100
Offspring 2	00010110001010**1101010010101101001010101**1

This form of recombination has several advantages. It possesses a greater number of variables that can be altered to study their effect. The size of the region of similarity, the degree of similarity required, where and how often within the region of similarity the recombination will occur, and the probability of recombination then occurring are all arbitrary values. The analogies of these values are poorly understood in natural systems and genetic algorithms can provide insight into their interactions. Also, unlike recombinational operators that predetermine the number of crossover points, this method has the inherent potential for multiple crossovers. In biological systems, the probability of multiple crossovers is often different from the simple product of individual events. This genetic property called *interference* has not yet been incorporated into genetic algorithms.

The recombinational model just described allows for the creation of recombinational hotspots and coldspots. Hotspots are regions where generalized recombination occurs with increased frequency; they are a common phenomenon in biological organisms. Hotspots would be invoked at the point of the probability check. The probability that recombination occurs once homology has been established could then be directly influenced by the sequence of the similarity. In addition to specific sequences influencing the probability of recombination, the probability could be made a function of the ratio of 1s to 0s, or it could depend upon the prevalence of repeated bits (analogous to the proposal that GC regions or perfect palindromes are hotspots in biological systems).

Homologous recombination is not the only means by which natural organisms recombine. Site-specific recombination occurs not because of sequence similarity but because of the recognition of certain sequences by specific proteins that bind to those sequences. The chemical pathways are not significant for genetic algorithms, but their results can be simulated to good effect. Typically, site-specific recombination removes, inserts, or copies

regions of DNA, as is the case with many transposons. Including an analogous function in genetic algorithms would allow another means of generating diversity among binary chromosomes. For example, in the chromosome below, the sequence 0000011111 is a transposable element that, at some probability, will move itself into the center of any sequence of 011001.

Parent 1 1101010011**0000011111**0011010110*110010*101011
Offspring 1 1101010011001101011011**0000011111**0010101011

Occasionally, in natural systems transposons will incorporate and relocate pieces of chromosomal DNA. Genetic algorithms can also model this behavior. For example, the previous transposable element could be made to recognize only the repeat 0s and 1s of the sequence, regardless of the code in between them.

Parent 1 1101010011**00000**10101**11111**0011010110*110010*
Offspring 1 1101010011001101011011**00000**1010**11111**0010

Such a system allows useful groups of code (i.e. genes) to be moved around the chromosome. Alternately, they could be deleted once excised, copied into the new location without being removed from their original site, inverted, or a combination of the latter two.

As with homologous recombination, site-specific recombinational techniques require many arbitrary values. The sequences recognized, the size of the transposable unit, the probability of a recombinational event occurring, and the rate at which each type of recombinational event occurs all must be given to the algorithm.

Most cells contain a great deal more DNA than that required for encoding their genes. Eukaryotic chromosomes are estimated to be up to 98% irrelevant DNA. These vast quantities of unused DNA are considered to be a sort of blackboard upon which evolution can scribble without affecting those regions of the chromosome encoding essential genes. Therefore, some expansion of the bit sequences available must occur. One means of doing this is to elongate the chromosomes with regions of "junk" sequence that are not included in the fitness evaluation.

Biological evolution is horizontal as well as vertical. Intergeneric recombination moves DNA between widely separated lineages. Plasmids and viruses move DNA from cell to cell with great promiscuity. Many prokaryotics are metabolically

adapted for the uptake of DNA they encounter in the environment. Given that natural organisms have a great deal more DNA than just their chromosomes, genetic algorithms could profit from analogous forms of binary code.

Regions of code that do not initially encode useful genes must at some point become recruited into the fitness evaluation if they are to ever be more than ''junk'' code. Regulation of which regions of the chromosome are to be used in the fitness evaluation is under the control of the chromosome in natural systems. Aspects of gene regulation and expression can be incorporated into genetic algorithms to provide similarity to natural systems. An analogy with promoter sequences can be used to determine which region of the chromosome is to be evaluated, thus defining the genes. They also make it possible to hand over some controls to the chromosome itself. For example, the probability that homologous recombination will occur could be given to the chromosome by encoding the probability value on the chromosome after a specific promoter. As a result, one of the variables that influences the generation of diversity is itself subject to genetic change. Any value usually specified in the structure of a genetic algorithm could be relocated to the chromosome in this way, in effect giving the chromosome the ability to alter its own means of changing. It is even possible to allow the chromosomes to evolve promoters by predefining both default values for the variables and the sequence of a promoter, initially absent from the population, which would encode the value of that variable. In this way, we hope to evolve genetic intelligence as the binary chromosome takes control of its own means of changing. New insights are almost certain to arise through the simultaneous study of carbon- and silicon-based life forms.

Keywords

Biological Evolution
A nondirected, dynamic process of diversification resulting from the steady interplay between spontaneous mutagenesis and natural selection.

DNA Rearrangement
Results from mostly enzyme-mediated recombination processes, which can be intra- or intermolecular.

Evolution Gene
Its protein product acts as a generator of genetic variations and/or as a modulator of the frequency of genetic variations.

Gene Acquisition
Results from horizontal transfer of genetic information from a donor cell to a receptor cell. With bacteria, this can occur in transformation, conjugation, or phage-mediated transduction.

Natural Selection
Results from the capacity of living organisms to cope with the encountered physicochemical and biological environments. Largely depending on its genetic setup and physiological phenotype, each organism may have either a selective advantage or a selective disadvantage as compared to the other organisms present in the same ecosystem.

Spontaneous Mutation
Defined here as any alteration of nucleotide sequences occurring to DNA without the intended intervention of an investigator. The term mutation is used here as a synonym of genetic variation.

Transposition
DNA rearrangement mediated by a mobile genetic element such as a bacterial insertion sequence (IS) element or a transposon.

Variation Generator
An enzyme or enzyme system whose mutagenic activity in the generation of genetic variation has been documented.

The comparison of DNA sequences of genes and entire genomes offers interesting insights into the possible evolutionary relatedness of genetic information of living organisms. Together with a relatively rich database from experimental microbial genetics, conclusions can be drawn on the molecular mechanisms by which genetic variations are spontaneously generated. A number of different specific mechanisms contribute to the overall mutagenesis. These mechanisms are here grouped into three natural strategies of the spontaneous generation of genetic variations: local changes of DNA sequences, intragenomic rearrangement of DNA segments, and acquisition of foreign DNA by horizontal gene transfer. These three strategies have different qualities with regard to their contributions to the evolutionary process. As a general rule, none of the known mechanisms producing genetic variants is clearly directed. Rather, the resulting alterations in the inherited genomes are more random. In addition, usually only a minority of resulting variants provide a selective advantage. Interestingly, in most of the molecular mechanisms involved, the products of so-called evolution genes are involved as generators of genetic variation and/or as modulators of the frequencies of genetic variation. Products of evolution genes work in tight collaboration with nongenetic factors such as structural flexibilities and chemical instabilities of molecules, chemical and physical mutagens, and random encounter. All of these aspects contributing to the spontaneous generation of genetic variations together form the core of the theory of molecular evolution. This theory brings neo-Darwinism to the molecular level. In view of the increasing evidence coming particularly from microbial genetics, knowledge of molecular evolution can be seen as a confirmation of Darwinism at the level of biologically active molecules, in particular, nucleic acids and proteins. Philosophical and practical implications of this knowledge will be briefly discussed.

1 Introduction

Evolutionary biology has traditionally devoted its major attention to the comparison of phenotypical traits of higher organisms, both of those actually living and of those that have been extinct (paleontological fossils). The resulting theory of descent is, together with other criteria, at the basis of the systematic classification of living organisms. Darwin's theory of natural selection brought a new element into the understanding of the long-term development of forms of life. Natural selection is the result of organisms coping with the encountered living conditions that are dependent on both the environmental physicochemical conditions and the activities of all living forms in a particular ecological niche. The Darwinian theory of evolution also postulated that intrinsic

properties of life are not entirely stable and principally identical for all organisms of a given species. In the so-called modern synthesis, in which evolutionary biology and genetics became integrated, transmissible phenotypic variations representing the substrate of natural selection were explained as due to genetic variations (or mutations). Shortly thereafter, deoxyribonucleic acid (DNA) was identified as the carrier of genetic information. DNA is thus also the target for mutagenesis. Within the last few decades a rapid development of molecular genetics with novel research strategies leading to genomics, sequencing of entire genomes, and functional studies of genes and their products paved the way for hitherto inaccessible knowledge on the basis of life and its multiple manifestations. This also relates to the process of molecular evolution. A synoptical insight into the various molecular mechanisms contributing to the generation of genetic variations represents a molecular synthesis between the neo-Darwinian theory and molecular genetics. This synthesis can confirm the Darwinian evolution at the molecular level.

2
Principles of Molecular Evolution

The principles of molecular evolution to be outlined here are founded on

1. the neo-Darwinian theory of evolution with its three pillars of genetic variation, natural selection, and isolation;
2. the solidly established microbial genetics database;
3. DNA sequence comparisons with bioinformatic tools;
4. physicochemical knowledge on the reactivity, conformational flexibility, and chemical stability of biologically active molecules.

2.1
Evolutionary Roles of Genetic Variation, Natural Selection, and Isolation

The long-term maintenance of any form of life requires a relatively high stability of its genetic information. However, rare occasional genetic variations occur in all organisms. This gives rise to mixed populations of organisms with the parental genome and organisms having one or more alterations in their genome. These populations are steadily submitted to natural selection. The experience shows that, in general, favorable genetic variations are considerably less frequent than unfavorable ones. The latter provide a selective disadvantage. Indeed, genetic variants with unfavorable genetic alterations will sooner or later get eliminated from propagating populations, which will become enriched for organisms carrying favorable genetic variations. It should be noted that by far not all alterations in the nucleotide sequences of a genome will lead to a change in the phenotype of the organism. However, such silent and neutral mutations may later become physiologically relevant in conjunction with still other, upcoming DNA sequence changes.

Natural selection is by no means a constant element. It varies both in time and in space. This is due to variations in the physicochemical environmental conditions as well as to variations of the life activities of all the different organisms present in a particular ecological niche and forming an ecosystem. Since a genetic variation may also affect the influence that the organism exerts on the other organisms present in the same ecosystem (e.g. think of weeds and pathogenicity

effects, but also of beneficial, synergistic effects), any novel mutation may not only influence the life of the concerned organism itself but also the lives of other cohabitants of the same ecological niche.

The third pillar of biological evolution – besides genetic variation and natural selection – is isolation. Evolutionary biologists define two different aspects of isolation. One of these is *geographic isolation*, which may seriously reduce the number of potential habitats for an organism. The other type of isolation is called *reproductive isolation*. For example, two distantly related diploid organisms may not be fertile in sexual reproduction. But reproductive isolation can also be seen in a wider definition to seriously limit the possibility of horizontal transfer of segments of genetic information between two different kinds of organisms.

As summarized in Fig. 1, genetic variation drives biological evolution. Complete genetic stability would render any

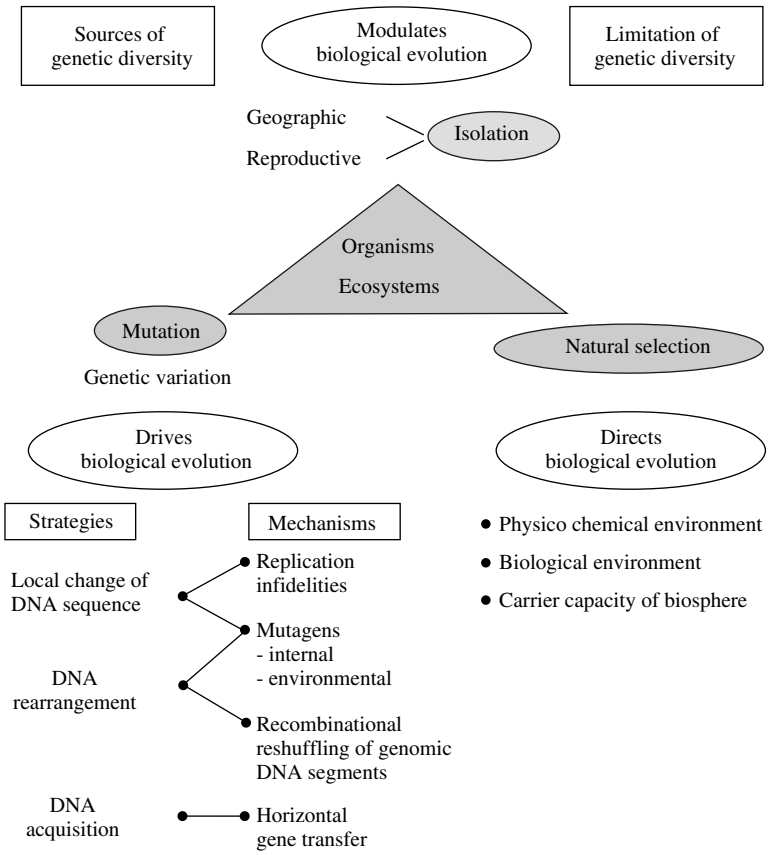

Fig. 1 Synoptical presentation of major elements of the theory of molecular evolution. A number of specific mechanisms, each with its own characteristics, contribute to the four groups of mechanisms of genetic variation listed. Each of the specific mechanisms follows one and sometimes more than one of the three principal, qualitatively different strategies of genetic variation.

evolutionary process impossible. A very high frequency of genetic variation would rapidly lead to the extinction of the concerned organisms because of the stated prevalence of unfavorable mutations in the spontaneous generation of genetic variations. It is natural selection together with the available sets of genetic variants that determines the direction of biological evolution, or in other words, the directions in which the branches of the tree of evolution grow. Finally, the geographic and reproductive isolations modulate the evolutionary process.

2.2 Molecular Mechanisms of the Generation of Genetic Variation

The concept to be presented here requires the reader to question some long-established textbook knowledge, such as the claim that spontaneous mutations would largely result from errors, accidents, and illegitimate processes. We defend here the alternative view that living nature actively cares for biological evolution

1. by making use of intrinsic properties of matter such as a certain degree of chemical instability and of structural flexibility of molecules, and
2. by having developed genetically encoded systems, the products of which are involved in the generation of genetic variations and in modulating the frequencies of genetic variation.

It might be relevant to mention here that the term mutation is differently defined in classical genetics and in molecular genetics. In classical genetics, a mutant is any variant of a parental form, showing in its phenotypic properties some alteration that becomes transmitted to the progeny. In contrast, it has become a habit in molecular genetics to call any alteration in the parental nucleotide sequence of the genome a mutation, whether it has phenotypic consequences or not. There is good reason to assume that in most spontaneously occurring mutagenesis events, the specific mechanism involved will not pay attention to whether the sequence alteration at the involved target site will cause a phenotypic alteration or not. Therefore, for studies on mechanisms and on the statistics of their occurrence, it is indicated to follow the molecular genetics definition of the term mutation, which we use here as a synonym of genetic variation. We will use the term *spontaneous mutation* to label any type of DNA sequence alteration unintended by the investigator. This definition says nothing about whether a mutation relates to a phenotypic change.

At present, the research on genetic variation mainly follows two strategies. First, the increasing availability of entire and partial genome sequences offers excellent means to compare regulatory sequence elements, specific domains of genes, entire genes, groups of genes, and entire genomes with regard to DNA sequence homologies and genome organization. Within a given species, this can reveal a genetic polymorphism. Between more or less related species, it can give a reliable measure for evolutionary relatedness. For example, the molecular clock – an indicator of evolutionary relatedness – is based on single nucleotide alterations. Sequence comparisons can often suggest how sequence alterations could have occurred in the course of past evolution. Secondly, a more reliable insight into the generation of genetic variations can be gained by the observation of individual processes of mutagenesis. In view of the large size of genomes and of the rare and random

occurrence of spontaneous DNA sequence alterations, this approach is relatively difficult. However, a rich database is already available from microbial genetics, particularly from bacteria and their viruses and plasmids. Their relatively small genomes are haploid so that phenotypic effects caused by genetic variation normally become rapidly manifested. With appropriate selection and screening techniques, this allows one to identify occasional, functionally relevant mutations in populations. On the other hand, investigations on structural alterations in the genomes of individual bacterial colonies, for example, by the study of restriction fragment length polymorphism, can reveal when and where on the genome a DNA rearrangement must have occurred.

A quite solid, general result of this type of experimental investigations reveals that in the spontaneous generation of genetic variations, it is not just a single mechanism at work. Rather, a number of mechanistically different processes contribute to the overall mutagenesis. We will discuss selected examples below. Interestingly, a critical evaluation of the situation shows that the specific mechanisms of mutagenesis often depend both on nongenetic elements and on activities of specific enzymes, the products of the so-called evolution genes. The multitude of thus identified, distinct mechanisms contributing to the formation of genetic variations can be grouped into three qualitatively different natural strategies (Fig. 1). These are

1. local changes in the DNA sequences,
2. rearrangement of DNA segments within the genome,
3. the acquisition by horizontal transfer of a DNA segment originating in another kind of organism.

Selected examples for each of these strategies will be discussed in Sects. 4, 5, and 6.

3 Genetic Variation in Bacteria

Several seminal discoveries, largely based on work carried out with microorganisms between 1943 and 1953, were essential for the later development of molecular genetics.

1. It was realized that bacteria and bacteriophages have genes that can mutate, and that spontaneous mutations in microorganisms normally arise independently of the presence of selective agents. It was also learned that the genetic information of bacteria and of some bacteriophages is carried in DNA molecules rather than in other biological macromolecules such as proteins.
2. The newly discovered phenomena of DNA transformation, bacterial conjugation, and bacteriophage-mediated transduction revealed natural means of horizontal gene transfer between different bacterial cells.
3. It was seen that horizontal gene transfer has natural limits, including systems of host-controlled modification, which are today known as *DNA restriction–modification systems*.
4. Mobile genetic elements were identified as sources of genetic instability and were seen to represent mediators of genetic rearrangements. While such rearrangements are often caused by transposition, they can also result from the integration of a bacteriophage genome into the genome of its bacterial host strain, which is thereby rendered lysogenic.

It is at the end of this fruitful period of discoveries, in 1953, that structural analysis of DNA molecules led to the double-helix model. The filamentous structure of DNA molecules made it clear as to how genetic information could be contained in the linear sequences of nucleotides. The double helical nature of the model also offered an understanding of semiconservative DNA replication at the molecular level and thus of information transfer into progeny.

Many classical microbial genetic investigations were carried out with *Escherichia coli* K-12. Its genome is a single circular DNA molecule (chromosome) of about 4.6×10^6 bp. In periods of growth, the rate of spontaneous mutagenesis is about 10^{-9} per bp and per generation. This represents one new mutation in every few hundred cells in each generation. *E. coli* has several well-studied bacteriophages and plasmids. This material facilitates investigations on life processes in these bacteria.

Under good growth conditions, the generation time of *E. coli*, measured between one cell division and the next, is very short, on the order of 30 min. Upon exponential growth, this leads to a multiplication factor of 1000 every 5 h. Thus, a population of 10^9 cells representing 30 generations is reached from an inoculum of a single cell in only 15 h. This rapid growth rate greatly facilitates population genetic studies and thus facilitates investigations on the evolutionary process.

On the filiform DNA molecules of *E. coli* and its bacteriophages and plasmids, the genetic information is relatively densely stored as linear sequences of nucleotides or base pairs. Genes depend on the presence of continuous sequences of base pairs (reading frames) that encode specific gene products, usually proteins, and of expression control signals that ensure the occurrence of gene expression at the relevant time with the needed efficiency. Mutations can affect reading frames as well as control signals, both of which represent specific DNA sequences. In addition, some specific DNA sequences relate to the control of the metabolism of the DNA molecules, in particular, their replication.

In the following Sects. 4, 5, and 6, we will describe selected examples of mechanisms contributing each in its specific manner to the formation of genetic variants. We will group them into the already mentioned three major natural strategies (Fig. 1), although, as we will later see, some of the specific mechanisms involve more than one of these strategies.

4
Local Changes in the DNA Sequences

The process of DNA replication is one of the important sources of genetic variation, which may depend both on structural features of the substrate DNA and on functional characteristics of the replication fork.

Some of the ''infidelities'' of DNA replication are likely to depend on tautomeric forms of nucleotides, that is, a structural flexibility inherent in these organic compounds. Base pairing depends on specific structural forms. Conformational changes of nucleotides can result in a mispairing if short-living, unstable tautomeric forms are ''correctly'' used in the synthesis of the new complementary strand upon DNA replication. For this reason, we do not consider mutations resulting in this process as errors and call them *infidelities*. DNA replication is indeed one of the sources of nucleotide substitution, and this plays an

important role in the evolutionary development of biological functions.

An inherent low degree of chemical instability of nucleotides represents another source of mutagenesis. For example, cytosine can undergo oxidative deamination to become uracil. Upon replication, this gives rise to an altered base pairing and results also in nucleotide substitution.

Other replication infidelities that may relate to slippage in the replication fork can result in either the deletion or the insertion of one or a few nucleotides in the newly synthesized DNA strand. If such mutations occur within reading frames for protein synthesis, the phenotypic effect may be drastic. This is the case when, in the protein synthesized from a gene affected by a frameshift mutation, the amino acid sequence downstream of the site of mutation strongly differs from that of the nonmutated product. In addition, the size of such a mutated protein is usually altered depending on the chance occurrence of an appropriate stop codon in the new reading frame.

Proofreading devices and other enzymatic repair systems prevent replication infidelities from producing mutations at intolerably high rates. Generally, they act rapidly after replication by screening for imperfect base pairing in the double helix. Successful repair thereby requires specific means to distinguish the newly replicated DNA strand from its template, the complementary parental strand. Because of these correction activities, many primary mispairings are removed before they have the opportunity to become fixed as mutations. DNA repair systems modulate the frequencies of mutagenesis.

Genetic information of some viruses, and sometimes also segments of genetic information of chromosomal origin, may pass through RNA molecules, which may later become retrotranscribed into DNA. No efficient repair systems are known to act at the level of RNA. Indeed, RNA replication shows a higher degree of infidelity than DNA replication. In consequence, genetic information that becomes replicated as RNA molecules generally suffers increased mutation rates.

A relatively large number of internal and environmental chemicals exert mutagenic effects by means of molecular mechanisms that in many cases are well understood and often cause local DNA sequence changes. Some intermediate products of the normal metabolic activities of a cell may be mutagenic and may thus contribute to spontaneous local mutagenesis. The mutagens of the environment include not only a multitude of chemical compounds but also ultraviolet radiation and some physicochemical constraints such as elevated temperature, which influence the chemical stability of nucleotides. Each of these mutagens and mutagenic conditions contributes in a specific way to the generation of genetic variations.

Again, many of the potential sequence alterations brought about by internal and environmental mutagens are efficiently repaired by enzymatic systems. However, since the efficiency of such repair is rarely 100%, evolutionarily relevant mutations persist.

5 Intragenomic DNA Rearrangements

Various recombination processes are well known to mediate DNA rearrangements, which often result in new nucleotide sequences.

While in haploid organisms general recombination is not essential for propagation, it influences genetic stability at

the population level in various ways as a generator of new sequence varieties. For example, it can bring about sequence duplications and deletions by acting at segments of homology that are carried at different locations in a genome. General recombination is also known to act in the reparation of damage caused to DNA by ionizing radiation. In this case, an intact genome can become assembled from undamaged segments of sister copies of the chromosome by homologous recombination. The best-known contribution of general recombination to genetic diversity is meiotic recombination bringing about random recombinants between the paternal and the maternal chromosomes in diploid organisms.

Two other widely spread types of recombination systems are dealt with in more detail in Sects. 5.1 and 5.2: site-specific recombination and transposition. Both are known to contribute to genetic variation. Still other recombination processes, such as the one mediated by DNA gyrase can, for the time being, perhaps best be grouped as illegitimate recombinations. This group may contain several different molecular mechanisms that act with very low efficiency and have remained at least in part unexplained.

5.1 Site-specific DNA Inversion at Secondary Crossover Sites

Genetic fusions represent the results of joining together segments of two genes (gene fusions) or of two operons (operon fusions) that are not normally together. An *operon* is a set of often functionally related genes that are copied into messenger RNA (i.e. transcribed) as a single unit. As a result of this organization, those genes are coordinately regulated; that is, they are turned on or off at the same time. Therefore, in an operon fusion, one or more genes are put under a different transcription control, but the genes *per se* remain unchanged. In contrast, gene fusion results in a hybrid gene composed of sequence motifs and often of functional domains originating in different genes.

In site-specific DNA inversion, a DNA segment bordered by specific DNA sequences acting as sites of crossing-over becomes periodically inverted by the action of the enzyme DNA invertase. Depending on the location of the crossover sites, DNA inversion can give rise to gene fusion or to operon fusion. The underlying flip-flop system can result in microbial populations composed of organisms with different phenotypic appearances: if, for example, the DNA inversion affects the specificity of phage tail fibers, as is the case with phages P1 and μ of *E. coli*, phage populations with two different host ranges will result.

Occasionally, a DNA sequence that deviates considerably from the efficiently used crossover site, a so-called *secondary crossover site*, can serve in DNA inversion, which thus involves a normal crossover site and a secondary crossover site. This process results in novel DNA arrangements, many of which may not be maintained because of lethal consequences or reduced fitness; but if a few new sequences are beneficial to the life of the organism, these may be selectively favored. This DNA rearrangement activity can thus be looked at as evolutionarily important. Since many different DNA sequences can serve in this process as secondary crossover sites, although at quite low frequencies, site-specific DNA inversion systems act as variation generators in large populations of microorganisms. I have thus postulated that this evolutionary role of DNA inversion systems may be more important than

their much more efficient flip-flop mechanism, which can at most help a microbial population to more readily adapt to two different, frequently encountered environmental conditions. As a matter of fact, other strategies could be used as well for the latter purpose.

Computer-aided comparison of DNA sequences quite often reveals that independent genes may consist of a particular domain with high homology and of other DNA sequences showing no significant signs of relatedness. DNA inversion using secondary sites of crossing-over is a potential source of such mosaic genes. DNA inversion can span over relatively large distances in DNA molecules and has the advantage of not loosing any DNA sequences located between the two sites of crossing-over. Deletion formation represents another source for gene fusion, but it has the disadvantage that the DNA sequences between the sites of crossing-over are usually eliminated.

5.2 Transposition of Mobile Genetic Elements

Nine different mobile genetic elements have been found to reside, often in several copies, in the chromosome of *E. coli* K-12 derivatives. This adds up to occupation of about 1% of the chromosomal length by such insertion sequences, also called *IS elements*. At rates on the order of 10^{-6} per individual IS element and per cell generation, these mobile genetic elements undergo transpositional DNA rearrangements. These include simple transposition of an element and more complex DNA rearrangements such as DNA inversion, deletion formation, and the cointegration of two DNA molecules. Because of different degrees of specificity in the target selection upon transposition, the IS-mediated DNA rearrangements are neither strictly reproducible nor fully random. Transposition activities thus also act as variation generators. In addition to DNA rearrangements mediated by the enzyme transposase, which is usually encoded by the mobile DNA element itself, other DNA rearrangements just take advantage of extended segments of DNA homologies at the sites of residence of identical IS elements at which general recombination can act. Altogether, IS elements represent a major source of genetic plasticity of microorganisms.

Transposition occurs not only in growing populations of bacteria but also in prolonged phases of rest. This is readily seen with bacterial cultures stored at room temperature in stabs (little vials containing a small volume of growth medium in agar). Stabs are inoculated with a drop of a bacterial culture taken up with a platinum loop, which is inserted (''stabbed'') from the top to the bottom of the agar. After overnight incubation, the stab is tightly sealed and stored at room temperature. Most strains of *E. coli* are viable in stabs during several decades of storage. That IS elements exert transpositional activities under these storage conditions is easily seen as follows.

A stab can be opened at any time, a small portion of the bacterial culture removed, and the bacteria well suspended in liquid medium. After appropriate dilution, bacteria are spread on solid medium. Individual colonies grown upon overnight incubation are then isolated. DNA from such subclones is extracted and fragmented with a restriction enzyme. The DNA fragments are separated by gel electrophoresis. Southern hybridization with appropriate hybridization probes can then show whether different subclones reveal restriction fragment length polymorphisms

(RFLPs), which are indicative of the occurrence of mutations during storage.

If this method is applied to subclones isolated from old stab cultures, and if DNA sequences from residential IS elements serve as hybridization probes, an extensive polymorphism is revealed. None or only little polymorphism is seen with hybridization probes from unique chromosomal genes. Good evidence is available that transposition represents a major source of this genomic plasticity observed in stabs, which at most allow for a very residual growth at the expense of dead cells. One can conclude that the enzymes promoting transposition are steadily present in the stored stabs. Indeed, the IS-related polymorphism increases linearly with time of storage for periods as long as 30 years. In a culture of *E. coli* strain W3110 analyzed after 30 years of storage, each surviving subclone had suffered on the average about a dozen RFLP changes as identified with hybridization probes from eight different residential IS elements, of which IS5 was the most active. Lethal mutations could of course not be identified in this study.

Lethal mutations that affect essential genes for bacteriophage reproduction can be accumulated in the prophage state of the phage genome in its lysogenic host. Such mutants can be screened for their inability to produce infective phage particles upon induction of phage reproduction. Experiments were carried out with *E. coli* lysogenic for a phage P1 derivative grown in batch cultures at 30 °C for about 100 generations allowing for alternative periods of growth and rest. Most of the independent lethal mutants could thereby be identified to be caused by the transposition of an IS element from the host chromosome into the P1 prophage that is maintained in its host as a plasmid. In these experiments, IS2 was the most active element and it mainly inserted into a few preferred regions of the P1 genome, but each time at another site. The used insertion targets did not show any detectable homology or similarity with each other. This is another good example for an enzymatically mediated variation generator. The experiment as such identifies IS transposition as a major source of lethal mutagenesis.

There is no evidence available that bacterial mobile genetic elements would play an essential role in the bacterial life span extending from one cell division to the next. However, these elements are major players in the evolution of bacterial populations. As we have seen here, they contribute to intragenomic DNA rearrangements. Depending on the target sequences involved, the resulting mutations may often be lethal by interrupting essential reading frames or expression control regions. Favorable mutations may be relatively rare, but these can contribute to evolutionarily advantageous developments of the genome. In Sect. 6, we will see that mobile genetic elements also play important roles in the natural strategy of DNA acquisition.

6 DNA Acquisition

While the mutagenesis mechanisms belonging to the strategies of local changes in the DNA sequences (Sect. 4) and of intragenomic DNA rearrangements (Sect. 5) are exerted within the genome and can affect any part of the genome, an additional strategy of spontaneous sequence alterations depends on an external source of genetic information. In DNA or gene acquisition, genetic information indeed originates from an organism other than

the one undergoing mutagenesis. In bacteria, DNA acquisition can occur by means of transformation, conjugation, or virus-mediated transduction. In the latter two strategies of horizontal gene transfer, a plasmid or a virus, respectively, acts as natural gene vector.

The association and dissociation of chromosomal genes with natural gene vectors often arises from transpositional activities and from general recombination acting at IS elements that are at different chromosomal locations. These mechanisms have been well studied with conjugative plasmids and with bacteriophage genomes serving in specialized transduction. For example, composite transposons, which are defined as two identical IS elements flanking a segment of genomic DNA (often with more than one gene unrelated to the transposition process), are known to occasionally transpose into a natural gene vector and, after their transfer into a receptor cell, to transpose again into the receptor chromosome. Hence, together with other mechanisms, such as site-specific and general recombination, transposition represents an important promoter of horizontal gene transfer.

Several natural factors seriously limit gene acquisition. Transformation, conjugation, and transduction depend on surface compatibilities of the bacteria involved. Furthermore, upon penetration of donor DNA into receptor cells, the DNA is very often confronted with restriction endonucleases. These enzymes cause a fragmentation of the invading foreign DNA, which is subsequently completely degraded. Before fragments become degraded, however, they are recombinogenic and may find a chance to incorporate all or part of their genetic information into the host genome. Therefore, we interpret the role of restriction systems as follows: they keep the rate of DNA acquisition low, and at the same time they stimulate the fixation of relatively small segments of acquired DNA to the receptor genome. This strategy of acquisition in small steps can best offer microbial populations the chance to occasionally extend their biological capacities without extensive risk of disturbing the functional harmony of the receptor cell by acquiring too many different functions at once. These considerations have their relevance at the level of selection exerted on the hybrids resulting from horizontal DNA transfer. This selection represents one of the last steps in the acquisition process.

DNA acquisition by horizontal gene transfer is a particularly interesting source of new genetic information for the receptor bacterium because the chance that the acquired DNA exerts useful biological functions is quite high – most likely, it has already assumed the same functions in the donor bacterium.

An interesting hypothesis links the universality of the genetic code with the important role played by horizontal gene transfer in the evolutionary development of the living world. According to this view, those organisms using the most common genetic language would, in the long term, be able to profit best from the increasing worldwide pool of genetic functions under the pressure of adapting to changing living conditions.

7 The Three Natural Strategies Generating Genetic Variations Contribute Differently to the Evolutionary Process

Biological evolution is a systemic process. As outlined above, many different specific mechanisms contribute to generate genetic diversity that represents at any time

the substrate for natural selection. The building up of functional complexity is a stepwise process, in which many random attempts of genetic alterations become rapidly rejected, while relatively few novel sequences are approved as favorable by natural selection and are maintained and amplified. The genome can thus be seen as a cabinet in which key information from favorable historical developments is stored. Stepwise, additional favorable information is added. In the context of changing selective conditions, stored information, having lost its functionally beneficial relevance, may be deleted or favorably altered. As we have seen, a multitude of different mechanisms are behind this dynamic process. For a better understanding of the events, we have grouped the identified mechanisms into three major natural strategies of genetic variation: local changes in the DNA sequences, intragenomic DNA rearrangements, and DNA acquisition. These three strategies have different qualities with regard to their contributions to biological evolution.

The local DNA sequence change is probably the most frequently involved strategy of genetic variation. Indeed, its frequency, which depends primarily on intrinsic properties of matter, chemical instability and conformational flexibility, would be intolerably high if it would not be modulated by efficient enzymatic systems of DNA repair. Local sequence changes bring about nucleotide substitution, the deletion and the insertion of one or a few base pairs, or a local scrambling of a few base pairs. These sequence changes can contribute to a stepwise improvement of a biological function. It must be kept in mind that the functional test for such improvement is carried out by natural selection. In principle, a long series of stepwise local sequence changes could also be expected to bring about a novel biological function. However, this kind of long-term process can gain efficiency only once natural selection starts to be exerted on such upcoming function.

In contrast, the reshuffling of DNA segments within the genome can be considered as a tinkering with existing elements, whereby favorable gene fusions and operon fusions may occasionally result. DNA rearrangement can also be the source of gene duplication and higher amplification, which are widely recognized contributions to the evolutionary progress.

In Sect. 6, we have already pointed to the evolutionarily high efficiency of horizontal gene transfer. As a matter of fact, DNA acquisition allows the recipient organism to share in the success of evolutionary developments made by others. In drawing the evolutionary tree of bacteria, DNA acquisition should be accounted for by more or less randomly adding temporal horizontal shunts between individual branches. It must be kept in mind that usually only small DNA segments flow through such shunts in horizontal gene transfer.

Several of the specific mechanisms of genetic variation employ, strictly speaking, more than one of the three strategies shown in Fig. 1. In transposition of IS elements, for example, a chromosomal DNA segment consisting of the mobile genetic element can undergo a translocation and thereby become inserted at a new target site. As a rule, the target sequence thereby gets duplicated, which usually involves a few nucleotides. Thus, this transposition event will consist of both a DNA rearrangement and a local sequence change.

As far as we know, most of the well-studied microbial strains use in parallel each of the three natural strategies for the generation of genetic variations. In

addition, bacteria very often use not only one, but several different specific mechanisms for mutagenesis by each of the strategies. Dissimilar specific mechanisms often work with different efficiencies as reflected by their contribution to the overall mutation rate. For any given strategy, it might be less relevant which specific mechanism is at work than the fact that the particular strategy finds its application with an evolutionarily useful efficiency. In other words, specific mechanisms may substitute for each other within a strategy, at least to some degree. This rule does not apply between the strategies because of the difference in the qualities of their evolutionary contributions.

The efficiency displayed by a given specific mechanism of spontaneous mutagenesis may depend on both internal (e.g. availability of enzymes that mediate mutagenesis) and external factors (e.g. environmental stress). It is also to be noted that some mechanisms may act more or less randomly along a DNA molecule, while other mechanisms may show regional or site preferences for their activities. In view of these considerations, we tend to assume that an evolutionarily fit (or well prepared) organism should best be able to use a few specific mutagenesis mechanisms for each of the three strategies to generate genetic variations. In Sect. 8, we will explain what we mean by evolutionary fitness.

8 Evolution Genes and Their Own Second-order Selection

The attentive reader will have seen in the description of some specific mechanisms contributing to the spontaneous mutagenesis that besides a number of nongenetic factors, specific products of genes are very often at work. These gene products can belong to systems for repair of DNA damage and will, in this case, modulate the frequency of mutagenesis. Similarly, restriction enzymes seriously reduce both the chance of DNA acquisition and the size of a DNA segment that may eventually be acquired by the recipient cell. Other gene products such as transposases and other mediators of DNA recombination act as generators of genetic variations. Since variation generators and modulators of the frequencies of genetic variation are evolutionary functions, we call the underlying genetic information *evolution genes*. In the microbial world, these evolution genes generally play no essential role in the physiology of individual lives going by cell division from one generation to the next. Under laboratory conditions, neither restriction–modification systems nor enzymes for DNA rearrangements are needed for the propagation of bacteria. The role of such enzyme systems is primarily evolutionary and becomes manifest at the level of populations.

We assume that evolutionary genes are themselves submitted to selective pressure. However, such selection cannot follow the rules of direct selection for improvements of essential functions such as those of housekeeping genes. Rather, the selection for the presence and improvement of a variation generator will be exerted at the level of populations. Clearly, it will also be an individual that may one day undergo a mutation, which improves an evolutionary function. This function will also be exerted in its progeny in which appropriate genetic variants of genes for directly selected products will be either more or less abundant. Any genetic alteration that affects an evolution gene and proves in the long term to be of higher evolutionary

value will be maintained and will provide an evolutionary benefit to the carrier of the involved gene. In the long run, this will lead to fine-tuning of the evolutionary functions of both variation generators and of modulators of the frequency of genetic variation. The underlying indirect selection based on the cells ability to provide genetic variants at a well-balanced level is called *second-order selection*.

We must be aware that some gene products may exert their essential functions for the benefit of both the life of the individual and the evolutionary progress of the population. In these cases, we assume that evolutionary selection is exerted for both kinds of functions and will eventually bring the gene to a fine-tuned state to optionally carry out its functions for each of the different purposes. However, as we have already mentioned, a number of gene products involved in genetic variation are inessential for the lives of individual bacterial cells. Similarly, the products of many housekeeping genes are inessential for biological evolution.

9 Arguments for a General Relevance of the Theory of Molecular Evolution for All Living Organisms

Largely on the basis of evidence from microbial genetics, we have so far postulated that the products of a number of evolution genes contribute, each in its specific way, to the generation of genetic variants at evolutionarily useful frequencies. Thereby, the sources of mutagenesis may relate either to the activity of the evolution gene product itself (e.g. a transposase) or to a nongenetic factor (e.g. a chemical mutagen or an intrinsic structural flexibility of a nucleotide). In many cases, nongenetic factors and products of evolution genes cooperate in the formation of genetic variants at physiologically tolerable and evolutionarily beneficial levels. This is, for example, the case in spontaneous mutagenesis by an environmental mutagen when some of the primary damage on the DNA gets successfully repaired while some other damage leads to a fixed mutation.

The theory of evolution postulates that life on Earth started almost four billion years ago with primitive, unicellular microorganisms. It is in the first two billion years that microbes must have developed the basis for the actual setup of evolutionary strategies and the underlying evolution genes. One can postulate that the acquired evolutionary capacities could have allowed some microbial populations to undergo a division of labor in more and more stable associations of cells. This development might later have led to multicellular organisms. In this kind of development, the evolutionary fitness of the involved organisms might have been an important precondition. At still later stages of further evolutionary development, the three natural strategies for generating genetic variations (Sects. 4 to 7) must have continued exerting their evolutionary influence together with some other factors such as the formation of symbiotic associations. As a matter of fact, we attach considerable evolutionary relevance to endosymbiosis of higher organisms with bacteria. Such situations of cohabitation may form an ideal condition for occasional horizontal gene transfer between the close associates.

A scientifically justified quest for further experimental proof of the postulates of the theory of molecular evolution remains quite difficult to be answered. Clearly, there is a need for research on

the spontaneous generation of genetic variation in higher organisms, ideally at the level of the genomes. While this is already quite difficult in microorganisms, it is of increased perplexity with the much larger genomes of higher organisms. However, sequence comparisons now offer fruitful ways to search for sequence homologies, sequence similarities, single nucleotide polymorphisms, as well as for traces of intragenomic DNA rearrangements and of horizontal transfer of genetic information. Data so far available are in support of the principles of molecular evolution outlined in Sect. 2, which are likely to be valid for any kind of living organism.

Some of the general evolutionary strategies developed in microorganisms must have also turned out to be useful for the developmental and physiological processes at somatic levels of higher organisms. The generation of antibody diversity in the immune systems of vertebrates by genetic rearrangements and so-called *somatic mutagenesis* is a good example. Another example is the enzymatic repair of DNA damage caused in somatic cells by external mutagens such as UV irradiation.

These considerations illustrate that whatever gene function may prove to be useful for whatever particular purpose, it may be evolutionarily retained and in the course of time further fine-tuned. We have already encountered this principle in the microbial world, where we have postulated multifunctional enzymes (such as working both for the physiology of the cells and for an evolutionary task) to become evolutionarily improved both by direct and by second-order selection for the various functions. This may also be the case in higher organisms.

10 Conceptual Aspects of the Theory of Molecular Evolution

With reference to Sect. 2.2, it is fair to again explicitly state that for the time being, evolution genes and evolution functions are a concept rather than a fully proven fact. This concept is based on a particular way to interpret numerous available experimental data. We will briefly analyze the difficulties to clarify the situation in a scientific debate. This will be followed by pointing to philosophical and more practical values of a deeper understanding of the molecular processes that drive biological evolution.

10.1 Pertinent Scientific Questions

In the history of scientific investigations, biologists have often searched for evidence that living organisms would be able to specifically modify, or adapt, their genetic information in order to better cope with upcoming changes in the living conditions. Most of these attempts have failed to give the expected response. In other cases, where a certain degree of specific adaptation could be observed, specific causal explanations have sometimes been found upon deeper investigation. However, there is at present no good scientific evidence for a general rule that genetic alterations would always be directed toward a specific goal. This situation favors the view that spontaneous mutations affect DNA more or less randomly, which is in line with the general observation that only a minority of spontaneous mutants prove to be favorable under the encountered living conditions.

The postulate of evolution genes that act as generators of genetic variations may be a surprise in this context. This has to do with a widely followed concept of genetic

information as a strict program for the fulfillment of a specific task. This definition does apply to many housekeeping genes, the products of which efficiently catalyze a reaction that reliably always yields the same product. This is not how a variation generator that does not work efficiently and that yields a different product from case to case functions. A good example is the transposition of mobile genetic elements. However, not all scientists see the primary function of a mobile genetic element in genetic variation. Rather, some colleagues interpret IS translocation, which often goes along with the replication of the element, as a selfish activity. This interpretation considers mobile genetic elements as parasites with the argument that their activity would often harm their host cell.

This discussion shows that the concept of evolution genes cannot easily be defended by referring to scientific evidence. Rather, the concept reflects an attitude of the observer of natural events. According to the view defended in this article, nature actively cares for biological evolution. The products of evolution genes are actively involved in generating different kinds of genetic variants at frequencies insuring both a certain genetic stability required for maintaining the concerned form of life and a low frequency of genetic variations as the driving force of evolution. This interpretation recognizes biological evolution as an essential principle of self-organization of life on Earth.

Another pertinent question that cannot find an easy scientific answer relates to the evolutionary function of viruses. At least some viruses are clearly identified to sometimes act as gene vectors in horizontal gene transfer. Some of them also temporarily integrate their genome into the host genome. This relates to the lysogenic state of bacteria as well as to endogenous viruses such as retroviruses that reside in many higher organisms. Again, one may wonder if these viruses primarily fulfill evolutionary functions for the evolutionary development of their hosts or whether they should rather be looked at as parasites that may carry out some evolutionary function by accident.

While prokaryotic organisms have genomes that are relatively densely packed with functional genes, many higher organisms have extended segments of intergenic DNA sequences, some of which are highly repetitive. Some of these noncoding sequences are highly homogeneous with regard to their nucleotide composition. While the biological roles played by noncoding regions are still not well understood, it has been postulated that compositional constraints may influence natural selection. These aspects have not been covered in this article and they may more specifically relate to the molecular evolution of higher organisms, in addition to the principles outlined here largely on the basis of evidence from microbial genetics.

10.2 Philosophical Values of the Knowledge on Molecular Evolution

One of the central questions of human curiosity is to know where life – and more specifically human life – comes from. The Darwinian theory opposed to the idea of a specific act of creation for each particular form of life, the alternative explanation of a steady evolutionary development implying the descent of the actual species from common ancestors. The directions of evolution are thereby given by natural selection acting steadily on all available forms of life

including all present variants. Until recently, the sciences could not specifically explain how genetic variants are generated. With recently developed research strategies, molecular genetics can now fill this gap. The branch of science called *molecular evolution* explains that there is not just a single source for genetic variants. Rather, many different specific mechanisms contribute to the generation of genetic variants at low frequencies. These mechanisms follow one and sometimes more than one basic strategies of evolutionary development. These are local changes in the DNA sequences, rearrangements of DNA segments within the genome, and acquisition of segments of foreign DNA by horizontal gene transfer. As a general rule, spontaneous mutagenesis is not specifically directed; it is at least to some extent random, so that only a minor fraction of spontaneous genetic variants turn out to be favorable for the concerned organism and thus provide it with a selective advantage. Nevertheless, new knowledge on the precise molecular mechanisms of the generation of genetic variations provides strong evidence that, in many cases, specific enzymes are involved – the products of evolution genes. These products work in tight collaboration with nongenetic factors that can be intrinsic properties of matter or environmental conditions. This view of the evolutionary process represents the core of a theory of molecular evolution and it can be seen as an extension of neo-Darwinism at the molecular level.

It should be clearly stated that the theory of molecular evolution does not explain the origin of life. It can, however, explain that biological evolution exerted in all living beings is a steady, dynamic process that is actively promoted not only by intrinsic properties of matter but also by the intervention of products of evolution genes or more generally of evolutionary functions of many different gene products. A recently published book devoted to these exciting insights is entitled *Darwin in the Genome*.

The high philosophical value of this extension of our worldview is obvious and merits to be widely discussed and evaluated in its various cultural dimensions. One interesting aspect is the implied duality of the genome. Indeed, evolution genes are located together with all the other genes on the genome and on accessory DNA molecules such as plasmids and viral genomes. While probably a major part of gene products carries out functions to benefit the cell and the individual, often a multicellular organism, probably a minority of gene products works for the biological evolution of the concerned population. Note, however, that the generation of a novel genetic variant obviously also occurs in an individual cell. But this act of creation has only a small chance to bring to the concerned cell and to its descendants a selective advantage. More often, the mutation is unfavorable and renders the life of the concerned organism more troublesome. As long as the spontaneous rate of mutagenesis remains low (mostly thanks to the intervention of evolution genes), unfavorable mutations are tolerable at the level of propagating populations.

Incidentally, the situation described here offers a possible explanation to the quite difficult theodicean question: why does God, despite His love for the human creature, admit that physically evil events such as a mutation causing an inheritable disease can occur to individuals? As a matter of fact, Genesis describes creation as a stepwise process, which implies the permanent evolutionary expansion of the diversity of life forms. Genesis also states that God evaluated this system as good.

Hence, biological evolution occurs according to God's intention to amplify diversity of life on our planet. Occasional unfavorable mutations affecting rare individuals in populations is a sacrifice brought to the creative force residing in the system of molecular evolution.

In brief, the genetic information contained in each genome – of bacteria as well as of all higher organisms – represents an internal duality. It serves individuals for the fulfillment of their individual lives and it serves populations for a slow but steady expansion of life forms and thus of biodiversity.

10.3 Aspects Relating to Practical Applications of Scientific Knowledge on Molecular Evolution

Living organisms today occupy an amazing variety of ecological niches on our planet Earth. These niches include extreme physicochemical conditions such as elevated temperatures, high pressure, and quite unusual compositions of chemical elements. However, despite the intrinsic potential of the living world to evolutionarily expand, one can estimate the carrying capacity of the planet for life to be in the order of 10^{30} living cells. Although this is a very large number, it seriously limits free expansion of life in its various forms.

The following reflections should help illustrate this statement. An adult human being carries in the order of 10^{13} cells. The human population today, thus occupies a share of about 10^{23} cells of the available 10^{30}. Incidentally, this happens to be close to the average available for each of the estimated 10^{7} different species of organisms on the planet. Bacteria propagate by cell division as outlined in Sect. 3. Extending the reflections made there, one can conclude that from an inoculum with one single bacterial cell, one can theoretically expect to obtain 10^{30} cells within only 50 h. In reality, growth will be stopped much earlier by lack of nutrition, but this reflection illustrates well the enormous internal forces for expansion of a given form of life.

Similarly, a high potentiality for evolutionary expansion toward more diversity resides in the mechanisms of molecular evolution that are described in this article. These mechanisms can serve us as a basis to better understand both the origin and the steady replenishment of biodiversity as well as the internal limits set to evolutionary expansion. This knowledge can and should increasingly be used as a background for any measures taken toward the protection of biodiversity and of habitats for diverse forms of life. Last but not the least, a better understanding of the evolutionary process can be of help to render the development of agricultural and related practices more sustainable.

Genetic engineering offers ample new possibilities for the sustainable production of medical drugs, to obtain food of higher quality, and to reduce the nocent impact of the human civilization on the environment. The serious reservations made by large parts of the human population impede many of the proposed biotechnological applications. A part of these concerns refer to unpredictable long-term effects of genetically modified organisms (GMO) that are released into the environment, such as in agricultural applications. Scientific assessments of long-term and, in particular, evolutionary effects of such applications are thus required. Knowledge of the natural strategies of molecular evolution can provide a good basis for such studies. As a matter of fact, in genetic engineering, DNA sequence alterations are

brought about within the genome by site-directed mutagenesis in studies of the biological functions of specific genes. In addition, well-defined segments of DNA are introduced into other organisms either in view of amplifying the particular DNA segment or in view of harvesting a specific gene product. GMO can also directly serve in applications as GM food and for bioremediation by microorganisms. A candid comparison of these practices involving genetic engineering with the natural strategies of generation of genetic variations reveals a high degree of similarities. The amounts of nucleotides or lengths of DNA sequences involved in these genetic modifications, both in genetic engineering and in the natural genetic variation, are of the same order of magnitude. Depending on the strategy involved, they may concern one to a few base pairs, or in other instances, a DNA segment containing a sequence domain or one to a few genes, both in intragenomic DNA rearrangements and in the horizontal transfer of DNA between two different organisms. Thus, one can principally expect that long-term evolutionary risks of GMO compare with the biohazard intrinsic to the natural process of biological evolution. Similar risks may also be inherent in classical breeding techniques.

These considerations ask for a more integral, holistic, and critical evaluation of the impact of past and present human activities on the natural process of biological evolution. Such assessments should address any human impact on genetic variation, natural selection, and isolation. As far as we know from the long-term history, the foundations of life and its evolutionary development on Earth are relatively robust. This is good news for us human beings, but it should not exempt us from a responsible and well-reflected use of our scientific knowledge in any attempt to render our own lives more easy and comfortable.

Oncogene
A gene that has a dominant transforming effect on normal host cells frequently mediated by growth factors, growth factor receptors, or intermediaries in the signal transduction process.

Small-cell Lung Cancer
A specific lung cancer histology in which the cells frequently contain neurosecretory granules. The cancers, often disseminated at diagnosis, initially respond well to chemotherapy but recur rapidly.

Tumor Suppressor Gene
A gene whose homozygous deletion or inactivation contributes to transformation of the host cell.

Lung cancer is a paradigm of carcinogen-induced human cancer. It is estimated that for every 3 million cigarettes purchased, a lung cancer follows 35 years later. Although the majority of lung cancers occurs in men, the incidence in women is rising rapidly in some regions.

Epidemiologic studies have irrefutably linked cigarette smoking and human lung cancer as well as other etiologic agents such as asbestos and radon. However, the molecular events within the cell that culminate in the development and progression of human lung cancer remain poorly understood. This is an important area for future research for several reasons. Elucidation of the molecular events in the genesis of lung cancer may have relevance to mechanisms for other carcinogen-induced tumors. Prevention, early diagnosis, and treatment strategies will be more rationally designed if they are based on molecular mechanisms.

The observation that genes responsible for carcinogenesis were altered forms of genes normally present in eukaryotic cells initiated many of the advances in molecular biology that have increased our understanding of lung carcinogenesis at the molecular level. Many of these genes have been implicated in the development of human cancer. An understanding of the molecular basis for lung carcinogenesis is essential for the development of improved methods of diagnosis, staging, treatment, and prevention for lung cancer.

The cell of origin for lung cancers is controversial. All histologies for non–small-cell lung cancer (NSCLC) have phenotypic features of the differentiated cell types in normal or injured bronchial epithelium. Small-cell lung cancer (SCLC) cells have neuroendocrine markers including high levels of the polypeptide hormones gastrin-releasing peptide and calcitonin, creatine kinase isoenzyme BB, L-dopa decarboxylase, and neuron-specific enolase. Endocrine cells can be found in normal bronchial mucosa. Thus, one possibility is that each of the four major histologies arises from alterations in its preexisting normal counterpart.

An alternative hypothesis is that the four types of lung cancer arise from a common stem cell and are related through a common differentiation pathway of the normal bronchial epithelium. This is supported by the clinical observation that SCLC tumors

can contain mixtures of SCLC and non-SCLC histologies. These transitions have been observed *in vitro* following insertion of the appropriate oncogene. For example, insertion of a mutated H-*ras* oncogene in SCLC cells with overexpression of c-*myc* causes transition to the large-cell undifferentiated phenotype.

1 Familial Predisposition to Lung Cancer

That the vast majority of cigarette smokers, including heavy smokers, do not develop lung cancer suggests the existence of an inherited predisposition or cofactors such as additional carcinogens. Studies have compared risk factors in individuals with histologically verified lung cancer and individuals with other smoking-related cancers. There was lack of increased risk of developing lung cancer when only lung cancer in relatives was considered. However, there was a significant excess of cancers at all sites for relatives of the lung cancer patients. This suggests a heritable variation in response to carcinogens. Respiratory diseases also predispose to development of lung cancer. Lung cancer families have been studied. The development of lung cancer in young individuals (50 or less) was compatible with Mendelian codominant inheritance of a rare autosomal gene. This gene was not involved for older persons, reflecting the medical history of noncarriers having long-term exposure to tobacco. The aryl hydrocarbon hydroxylase gene product can metabolize promutagenic and procarcinogenic compounds in cigarette smoke. The aromatic hydrocarbon-inducible cytochrome P4501 A I gene is highly expressed at the RNA level in normal lung from active cigarette smokers, but not in normal lung from nonsmokers. The ability to metabolize debrisoquine is genetically determined and is associated with susceptibility to lung cancer. Studies have shown that the ability to metabolize debrisoquine is independently associated with susceptibility to lung cancer in a case–control study.

The rapid development of technology in molecular biology has resulted in the identification of genetic alterations in human lung cancer. However, the plethora of genetic abnormalities detected has created some confusion as to their significance in the genesis and progression of lung cancer. Small-cell lung cancer has been extensively studied, partly because of the availability of many established SCLC cell lines that can be grown in serum-free, chemically defined media. However, only 20% of lung cancers are of the small-cell type. Furthermore, the biologic behavior of SCLC is quite distinct from NSCLC. SCLC disseminates early in its course and exhibits a marked sensitivity to chemotherapy followed by early recurrence. Thus, it is possible that genetic events in SCLC and NSCLC may differ. Recent studies summarized here indicate differences. Thus, molecular mechanisms may not be generalizable among the different forms of lung cancer. The relative importance and sequence dependence of these genetic alterations in the genesis and progression of lung cancer is unknown.

This article summarizes areas of recent investigation of molecular events in human lung cancer including oncogene

activation and inactivation of tumor suppressor genes. Table 1 lists the genes that have been implicated in lung carcinogenesis.

2 Oncogene Activation

2.1 *myc* Family

One of the first specific genetic changes associated with lung cancer was the observation that the c-*myc* oncogene was amplified in a subgroup of SCLC cell lines. The SCLC cell lines having an amplified c-*love* gene are morphological and biochemical variants of SCLC (SCLC-V). SCLC-V cell lines have a rapid doubling time, higher cloning efficiency, increased tumorigenicity, and increased resistance to X-rays compared to SCLC. In addition, SCLC-V cell lines do not express L-dopa decarboxylase or peptide hormones, which are typically expressed on cells of neuroendocrine origin. They are distinguished from NSCLC, however, by having elevated levels of the BB isoenzyme or creatine kinase and neuron-specific enolase. It has been reported that SCLC-V cell lines showed high levels of c-*myc* amplification and c-*myc* mRNA levels. Only one NSCLC cell line out of five in the report showed c-*myc* amplification. The c-*myc* gene was transfected into the H209 classic SCLC cell line. One of the transfectants expressing high levels of c-*myc* had an increase in doubling time and increased cloning efficiency, but L-dopa decarboxylase levels and bombesin-like immunoreactivity were unchanged.

Amplification of c-*myc* was observed in both classic and variant SCLC cell lines. However, c-*myc* mRNA levels were more elevated in the variant cell lines. Three classic lines had amplification of N-*myc* RNA and one variant line had amplification of N-*myc* and *myb*. Three SCLC-V cell lines showed high levels of a *v-fms*-related transcript related to but not identical with the *CSF 1I* receptor. Subpopulations of SCLC cells with intermediate neuroendocrine differentiation have been identified. The cell lines expressed some neuroendocrine markers such as L-dopa decarboxylase, but not others such as bombesin and neurotensin. These cell lines also had high levels of c-myc protein. Expression of c-myb protein was seen for two cell lines in which c-myc expression was low or not detectable. Expression of c-rafl protein was low in 11 of the 12 cell lines. Four of five NSCLC cell lines expressed c-myc protein at high levels, and these were all of the large-cell undifferentiated morphology. In another study, 3 of 27 NSCLC DNA samples from primary tumors had amplification of the c-*myc* gene. Others have identified high levels of c-*myc* mRNA in an NSCLC cell line in the absence of DNA amplification. Run-on transcription studies for this cell line showed that the transcriptional rate *for* c-*myc* was high.

Analysis of SCLC cell lines for c-*myc* amplification revealed additional EcoRl restriction fragments suggesting *myc*-related

genes. A third gene in the *myc* family, L-*myc*, was cloned and showed homology to c-*myc* and N-*myc*. Four SCLC cell lines had amplified L-*myc* genes. The L-*myc* gene has been cloned and sequenced and consists of 3 exons and 2 introns spanning 6.6 kb of human DNA. There is homology with discrete regions of N-*myc* and c-*myc*. The L-*myc* gene encodes a series of nuclear phosphoproteins that arise by alternative mRNA processing. L-*myc* can cooperate with an activated c-Ha-ras to transform primary rat-embryo fibroblasts. However, the transforming efficiency was 1 to 10% of that seen with c-*myc*. One study found a correlation between restriction fragment length polymorphisms (RFLPs) of the L-*myc* gene and lymph node metastases in NSCLC. The presence of either the S band (6 kb) or the S and L (10 kb) bands was associated with lymph node metastases.

Amplification and increased expression of the N-*myc* gene occurs in SCLC and NSCLC. Expression of N-*myc* in SCLC biopsies was detected by *in situ* hybridization. Increased expression was associated with poor response to chemotherapy and short survival. Amplification of N-*myc* gene sequences ranging from 5- to 170-fold was observed in SCLC cell lines. Both c-*myc* and N-*myc* were amplified, but only one member of the myc family was amplified in any one cell line. Amplification of N-*myc* has been reported in an adenocarcinoma of the lung. Others have found amplification of one of the *myc* family in 2 of 12 SCLC cell lines. Again, only one member of the family was amplified in each cell line. All cell lines had deletions of chromosome 3. When fresh tumor specimens were analyzed, amplification and rearrangement of *myc* genes was heterogeneous. N-*myc* or L-*myc* amplification was noted in 4 of 17 small-cell cancers. Amplification of c-*myc* was seen in 3 of 12 non–small-cell lung cancers. In some cases, amplification was seen in the primary tumor but not metastases. In two cases, amplification was seen only in cell lines, not in the original tumors. Expression of *myc* family genes was demonstrated in SCLC cell lines and nude-mouse xenografts using *in situ* hybridization techniques. The molecular mechanisms regulating the expression of each of the *myc* family genes are complex. Both c-*myc* and L-*myc* mRNA showed loss of transcriptional attenuation, which correlated with overexpression seen in cell lines without gene amplification. Regulation of N-*myc* expression correlated with promoter activity and gene amplification.

An interesting association between responsiveness to bombesin and *myc* family expression has been noted by one investigator. SCLC cell lines responsive to bombesin showed constitutive expression of L-*myc*. Nonresponsive cell lines expressed N-*myc* or c-*rnyc*.

The significance of increased expression of *myc* family genes remains uncertain. Initially, c-*myc* amplification was described in SCLC cell lines with variant morphology. This variant morphology is also called *small-cell/large-cell carcinoma* and is thought to indicate an unfavorable prognosis. Cell lines with the variant morphology have relatively more resistance to chemotherapy and radiation therapy. However, review of pathology specimens of patients with extensive-disease SCLC showed that the variant cell type was rare, occurring in only 4.4% of 550 specimens. There were no significant differences in response rates to chemotherapy or prognosis for patients with ''classic'' compared with variant morphology. Amplification of the c-*myc* gene was more frequent in cell lines from SCLC patients with tumor relapse than in untreated patients. Amplification of c-*myc* was associated with

shorter survival in relapsed patients. The role of increased expression of *myc* family genes in the genesis of lung cancer requires further definition. It is likely that increased c-*myc* expression leads to progression of SCLC; it appears unlikely to be a primary event because it is detected in a minority of tumors. The association of increased c-*myc* expression with the variant cell type and the significance of this cell type require additional clarification. Increased expression may occur by several mechanisms and is not always associated with gene amplification. Alterations in *myc* expression in NSCLC have not been extensively studied, but in one case several NSCLCs showed increased expression of c-*myc*.

2.2 *ras* Family

Oncogenes of the ras family (homologous to the rat sarcoma vines) have three primary members (H-*ras*, K-*ras*, and N-*ras*) and are among the most common activated oncogenes found in human cancer. The *ras* genes code for a protein that is located on the inner surface of the plasma membrane, have GTPase activity, and may participate in signal transduction. *ras* oncogenes are activated by point nucleotide mutations that alter the amino acid sequence of p21.

2.3 *ras* in Carcinogen-induced Tumors

Studies in mice with carcinogen-induced lung cancers implicate genes of the ras family in the carcinogenesis process. Mouse lung tumors induced by tetranitromethane contained mutated K-*ras* genes. Mice harboring the mutated H-*ras* transgene developed tumors exclusively in the lungs within weeks of birth. Lung tumors can be induced in mice with the tobacco-specific nitrosamines 4-(*N*-methyl-*N*-nitrosamino)-1-(3-pyridyl)-1-butanone (NNK) or nitrosodimethylamine (NDMA). Ninety percent of these tumors had transforming genes in the NIH3T3 assay, and in all lung tumors, this was K-*ras*. The mutations were generally GC-to-AT transitions, indicating that DNA methylation is the most likely pathway to the induction of neoplasia by these carcinogens.

2.4 Human Studies

Amplification of *ras* oncogenes is uncommon in lung cancer. Heighway and Hasleton found no amplification of K-*ras* in 25 primary specimens. However, in one study a lymph node metastasis showed 30-fold amplification of K-*ras*. Expression of p21 as measured by binding of monoclonal antibody rp-35 increases with increasing size of the primary tumor.

Activation of the K-*ras* oncogene by point mutation occurs in lung cancer cell lines. A mutation in codon 12 (glycine to cysteine) occurs in *Calu* 1 and in codon 61 in *PR310* (glutamine to histidine). RFLP analysis for a codon 12 mutation (glycine to arginine) did not show any mutations in 24 primary NSCLC lung cancers. Other mutations have been detected in the 12th codon using a highly sensitive technique based on amplification with the polymerase chain reaction and detection with a panel of oligonucleotide probes. K-ras mutations in most studies were confined to adenocarcinomas of the lung and occurred in 30% of tumors. Mutations were not observed in adenocarcinomas from nonsmokers. K-ras mutations appear to be an independent prognostic factor, indicating

a poor prognosis, and are unrelated to conventional staging criteria such as tumor size or lymph node metastases. In all patients studied, mutations occurred in a single allele.

ras mutations can also influence the differentiation of tumor cells. For example, infection of SCLC cell lines with the Harvey murine sarcoma virus alters the phenotype of variant cells but not that of classic cells. Following infection, the variant SCLC cell line developed features of a large-cell undifferentiated lung carcinoma including increased carcinoembryonic antigen (CEA) and keratin expression.

Studies done to date favor the interpretation of *ras* activation as a progression factor in lung cancer. It apparently is activated in about one-third of adenocarcinomas arising in patients with a heavy smoking history. Antisense (AS) technology has been used to find the effects of eliminating expression of a mutant K-*ras* oncogene in NSCLC cells. A homozygous mutation at codon 61 was detected in the NCI-H460a large-cell undifferentiated NSCLC cell line clone with a normal glutamine residue (CAA) substituted by histidine (CAT), using hybridization with specific oligonucleotide probes. An AS K-ras RNA construct selectively blocked the production of mutant p21, allowing investigators to study the contribution of the mutated p21 protein to the malignant phenotype. A recombinant plasmid clone was constructed using a wild-type, 2-kb K-ras genomic DNA segment carrying second and third exons with flanking intron sequences subcloned into an Apr-I-neo expression vector in AS orientation. The intron sequence used has a low degree of homology with other *ras* genomic sequences, leading to specific inhibition of K-*ras* with preservation of H-*ras* and N-*ras* expression. Previous studies on uptake of *ras* AS oligonucleotides by cancer cells resulted in cell death instead of regulated growth. This is probably because functional p21 protein is necessary for cell viability, and the oligonucleotides unselectively blocked *p21* expression produced by all three members of the *ras* gene family. Unselective blockade of oncogene expression can therefore be toxic to both normal and cancer cells. The 2 kb DNA insert was stably integrated into H460a cells as shown by Southern hybridization. Northern blot analysis detected expression of AS RNA. Western blot analysis showed 95% reduction in K-ras p21 protein synthesis in the clones expressing the AS RNA, while H460a cells and sense K-*ras* clones showed unchanged levels of K-*ras* p21 protein. Total p21 detected with a pan-ras monoclonal antibody showed only a slight decrease in the AS clones, suggesting that other ras genes were not affected. AS transfectants showed a threefold reduction in growth compared to sense transfectants and parental H460a cells but continued to grow in culture. Expression of AS K-*ras* RNA reduced the growth rate of H460a tumors in nu/nu mice. Tumorigenicity of cell lines expressing AS RNA was assessed by subcutaneous injection of 10^5 cells in nu/nu mice. Unmodified H460a cells formed tumors in all mice in 15 days. No tumor developed in mice injected with H460a AS cells during 120 days of observation, while H460a cells transfected with *Apr-I-neo S* plasmid formed tumors similar to H460a cells. These experiments show that in H460a cells engineered to synthesize AS K-*ras* RNA, the levels of K-ras mRNA and K-ras p21 protein are dramatically reduced. Thus, a recombinant construct can be made that distinguishes among members of the ras family. AS RNA generated from the genomic DNA

of the K-*ras* gene can thus specifically inhibit K-ras expression. Inhibition of K-ras reduced the growth rate of H460a cells but did not alter cell viability or continued growth in culture. This suggests that redundancy in p21 expression may compensate for absence of expression by one member of this family so that functions essential for maintenance of cell viability are preserved. This technique provides an opportunity to determine the effects of selective inhibition of oncogenic protein expression on the malignant phenotype. This study and subsequent confirmatory ones showed that reversal of a single genetic abnormality was sufficient to prevent human cancer cells from forming tumors. Thus, reversing all the genetic lesions in a cancer cell is not necessary for a therapeutic effect. These observations raise the intriguing possibility of specific gene therapy for cancer. Sequences could be delivered to tumor cells via viral vectors that specifically inhibit expression of the oncogenes activated in the cancer cell. Such constructs would be relatively nontoxic because, as in the preceding example, they could target a single gene whose function might be subsumed by other redundant genes of the same family. Thus, repeated infusions of immunologically distinct vectors could be performed. Retroviral vectors have the added advantage of being incorporated in the genome of only cells that replicate, thus favoring integration in cancer cell DNA.

Sporadic alterations in a variety of other oncogenes have been described. Amplification of c-*erb B-1*, c-*myc*, and c-*myb* as well as deletions in c-H-*ras* and c-*myb* have been reported. Expression of multiple protooncogenes in SCLC was determined in one study using Northern analysis. Increased expression of *myc* family genes was confirmed. ras family and c-*raf I* were expressed in all cell lines. Other oncogenes including c-*fes*, c-*fos*, c-*erb B-1*, c-*mos*, c-*sis*, c-*erb A*, c-src, and c-*abl* were expressed weakly or not expressed at all. Components of telomerase including the RNA (hTR) and enzyme activity (hTERT) are expressed at high levels in lung cancers and may provide a mechanism for cellular immortality.

3 Growth Factors and Autocrine–Paracrine Growth Control

Tumor cells that produce a growth factor and express its receptor may show self-stimulatory or autocrine growth. Cells that are regulated by an autocrine loop have several features. They secrete a biologically active growth factor and demonstrate increased proliferation to that factor. Antibodies that bind specifically to the growth factor will inhibit cell growth. Growth factors may act to stimulate growth in adjacent cells in a paracrine manner. Interaction of ligand and receptor in the cytoplasm of the cell may result in the formation of an internal autocrine loop.

Autocrine growth factors have been implicated in the stimulation of SCLC cell growth. The majority of SCLC cell lines produce bombesin. This 14–amino acid peptide is identical to a carboxyterminal heptapeptide sequence of a mammalian analogue, gastrin-releasing peptide. SCLC cell lines express a single class of high-affinity, saturable binding receptors for bombesin. Bombesin is also a potent stimulator of clonal growth for human NSCLC. Bombesin receptors have not been demonstrated on NSCLC. Oncogene products related to growth factor receptors of the tyrosine kinase family are implicated in retrovirally induced neoplasia. For

example, *v-erb B*, the transforming gene of avian erythroblastosis virus, codes for a truncated version of the epidermal growth factor receptor (EGFR). Activation of the overexpressed normal receptor gene appears to be sufficient for transformation of NIH 3T3 cells. NSCLC cells express high levels of functional EGFR. This is an uncommon finding for SCLC. NSCLC cells also show amplification of the *EGFR* gene. This suggests that growth factors and their receptors may play an important role in the development and/or maintenance of the malignant phenotype. In contrast to SCLC, autocrine growth control mechanisms have not been clearly defined for NSCLC. Studies have suggested that insulin-like growth factor I (IGF-I) may participate in autocrine growth stimulation.

3.1 c-*erb B-2*

c-*erb B-2* is a member of the EGFR family, which comprises three genes with a receptor-like structure: an external Iigand binding domain, a transmembrane domain, and a cytoplasmic tyrosine kinase domain. The *neu*/c-*erb B-2* oncogene was first identified in an ethylnitrosoureainduced rat neuroblastoma. The rat oncogene is activated by a point mutation, but the mechanism in human cells appears to be overexpression. The gene has homology to the *EGFR* gene, and the gene product (185 kDa) is a tyrosine kinase. The structure of this protein is receptor-like and several ligands have been identified. The *erb 13-2* gene is activated in NSCLC. In one study, amplification of the c-*erb B-2* occurred in only 10% of 60 paired samples of NSCLC and normal lung. However, adenocarcinomas showed high mRNA levels of c-*erb B-2*. In contrast, *SCLC* cells did not express c-*erb B-2*. A study of freshly excised surgical specimens confirmed and extended these findings. NSCLC specimens showed high levels of c-*erb B-2* RNA expression in 6 of 16 samples compared to paired normal lung samples. Increased expression occurred in both early and advanced stages. Fresh SCLC showed minimal or no expression. In a study using immunohistochemical techniques, expression of the c-*erb B-2* gene product, p185, occurred at higher levels in the tumor than in bronchiolar epithelium. The investigators found that c-*erb B-2* expression in adenocarcinomas is independently correlated with diminished survival.

3.2 TGF-α

Transforming growth factor type alpha (TGF-α) is a single polypeptide of 50 amino acids that is derived from a 160–amino acid transmembrane precursor by proteolytic cleavage. TGF-α is structurally and functionally related to the epidermal growth factor (EGF) and it binds to the EGFR. TGF-α alone does not transform normal rat kidney (NRK) cells. Anchorage-independent growth is seen when TGF-α and TGF-β are added together. TGF-α is a candidate autocrine growth factor for NSCLC. Earlier studies indicated that medium conditioned from A549 lung carcinoma cells can promote the growth of human NSCLC cells in culture. This conditioned medium is known to contain TGF-α, and exogenous TGF-α added to cultures increased colony formation.

It appears that it is not necessary for TGF-α to be cleaved from its conserved integral membrane glycoprotein to have biologic activity. When baby hamster kidney (BHK) cells were transfected with an expression vector containing altered sequences, the cells did not secrete TGF-α but expressed the pro-TGF-α on the cell

surface. The membrane-bound pro-TGF-α bound to EGFR on A431 cells and induced receptor autophosphorylation. Solubilized pro-TGF-α induced tyrosine autophosphorylation of EGFR in intact receptor-expressing cells and stimulated anchorage-independent growth of NRK fibroblasts. Thus, both pro-TGF-α and TGF-α could function as autocrine growth factors. Possibilities include interaction of pro-TGF-α with a cytoplasmic form of the EGFR as well as with EGFR expressed on adjacent cells.

The presence of EGFR on lung cancer cells suggests that an autocrine/paracrine growth mechanism may be operative. This possibility was investigated *in vitro* with cloned NSCLC cell lines. None of the cell lines expressed EGF by Northern analysis. All cell lines expressed TGF-α mRNA. TGF-α binds to the EGFR and therefore the investigators studied the biologic response to and production of TGF-α by these cell lines. Each cell line expressed EGFR by [I^{125}]EGF competitive binding and Scatchard analysis and by phosphorylation. The receptors were functionally active as determined in immune-complex kinase assays. The cloned NSCLC cell lines H322a, H226b, H596b, and H460a showed stimulated uptake of tritiated thymidine in response to both TGF-α and EGF. Exogenously added TGF-α increased colony formation in soft agar for three of the four cell lines in media containing serum. All cell lines expressed some TGF-α mRNA, although to differing degrees. Cell lysates and spent media competed for EGFR binding with EGF, thus showing production of TGF-α-like activity.

There was heterogeneity in the mechanism of autocrine growth stimulation among the four cell lines. H322a and H226b cells were specifically growth-inhibited by the anti-TGF-α monoclonal antibody AB-3 at low cell density, suggesting that the antibody blocks an autocrine growth loop. This inhibition was dose-dependent and did not occur following addition of the isotope identical to monoclonal antibody MOPC21. However, the AB-3 antibody did not alter the growth of H460a and H596b cells even though these cells express EGFR and secrete TGF-α. Suramin, which blocks binding of ligand to receptor in other autocrine systems, inhibited the growth of both cell lines. Addition of TGF-α specifically reversed inhibition by suramin. Addition of platelet-derived growth factor did not reverse suramin inhibition. This suggests that autocrine activation for this cell line occurred in the intracellular compartment between unprocessed receptor and unsecreted ligand. TGF-α appears to be an important autocrine growth factor for NSCLC cells of both squamous and adenocarcinoma histologies.

4 Tumor Suppressor Genes

The inactivation of certain genes may contribute to tumor growth. In one scenario, both copies of the gene must be eliminated or inactivated to eradicate the growth-suppressive function of the gene. Because both copies must be eliminated, the tumor suppressor gene is called *recessive*. The retinoblastoma *(Rb)* gene supports this model. Patients with familial predisposition have a germ line inactivation of one copy of the *Rb* gene. The tumor develops when the wild-type allele is either inactivated or deleted. This model has spawned multiple studies searching for consistent chromosomal deletions in human tumors.

One of the earliest and most consistent chromosomal deletions in lung cancer

occurs in chromosome 3 (p14–p23) for SCLC. Cytogenetic studies of fresh tumors confirmed observations on cell lines. Allelic loss in this region was documented with polymorphic DNA probes and occurred at a high frequency. Loss of heterozygosity for alleles on chromosomes 3, 11, 13, and 17 occurs in NSCLC as well. The high frequency of chromosomal deletions for both SCLC and NSCLC has suggested that loss of specific gene function may be a critical step in the development of lung cancer. Two candidate suppressor genes are the nuclear oncogenes *p53* and *Rb*.

Loss of heterozygosity on chromosome 13q suggests that the *Rb* locus, located at I3q14, may be deleted. Studies show that up to 60% of SCLC and 75% of carcinoid cell lines do not express *Rb* mRNA. However, 90% of NSCLC cell lines expressed *Rb*.

The *p53* gene encodes a 375–amino acid phosphoprotein that can form complexes with viral proteins such as large T-antigen and E 113. Missense mutations are common for the *p53* gene and are essential for the transforming ability of the oncogene. The mechanism of p53 transformation is controversial. The *p53* gene appears multifunctional, with major domains that can transactivate, bind proteins, bind sequence-specific DNA, and oligomerize with p53. Abnormalities in one or more of these functions could contribute to abrogation of the tumor suppressor function of *p53*. Certain mutations also have a dominant transforming capability. The wild-type *p53* gene may suppress genes that contribute to uncontrolled cell growth and proliferation or activate genes that suppress uncontrolled cell growth. Thus, absence or inactivation of wild-type p53 may contribute to transformation. However, some studies indicate that the presence of the mutant p53 may be necessary for full expression of the transforming potential of the gene.

Mutations of *p53* are common in a wide spectrum of tumors. These mutations occur in both NSCLC and SCLC cell lines and fresh tumors. The precise role of these mutations in oncogenesis and the mechanisms involved are subjects of active investigation. Mutations in *p53* positively correlate with lifetime cigarette consumption. Radon exposure, which increases lung cancer risk, is also associated with *p53* mutations, although the mutation types differ from those seen in tobacco-associated lung cancer. Insertion of a wild-type *p53* in lung cancer cell lines with a mutant or deleted *p53* can suppress their growth, even though the cells have multiple genetic lesions. The p53 protein may be overexpressed in lung cancer cells, although this effect is not always associated with the presence of a mutant *p53* gene. However, overexpression of the p53 protein has correlated positively with a poor prognosis. Deletions in 171, *p53* mutations, and 3p deletions have been detected in preneoplastic lesions of the lung such as severe dysplasia. Mutations in *p53* and *ras* appear to be independent events.

A common theme with many of the genetic lesions occurring in cancers is their relationship to regulation of progression through the cell cycle. Premature entry of cells into the next phase of the cell cycle may prevent completion of important molecular events such as DNA repair and may lead to genetic instability. The cell cycle may pause at both the G1 and G checkpoints. Phosphorylation of the Rb protein will release the transcription factor *E2F* and mediate transition across the G_1 checkpoint. Inactivation of *Rb* by mutation or deletion could therefore cause a state of activation. A gene encoding an inhibitor (called variously p21, WAF-1, Cip1, or

Sdi1) of the cyclins – the proteins that mediate cell cycle progression – is one of the downstream effectors of *p53* and mediates G1 arrest. Another inhibitor of the cyclin system is *p16*. This gene is frequently inactivated in many cancers including lung cancer.

Tumor suppressor genes that less frequently inactivate in lung cancers include *PTEN, hOGG1* (DNA repair), and *BAP1* (ubiquitination). The primary mechanism of inactivation of expression of the majority of tumor suppressor genes identified to date is promoter hypermethylation. Frequent inactivation of expression by promoter methylation has been observed for *APC, CDH13, RARβ, FHIT, RASSF1A, TIMP3*, *p16*, *MGMT*, and *DAPK*. Methylated DNA sequences can also be detected in the bronchial epithelium from smokers without lung cancer.

5 Premalignancy and Second Primary Cancers

Many of these molecular alterations have been identified in lung epithelium of current and former smokers without lung cancer. Such changes are almost never found in true lifetime nonsmokers (less than 100 cigarettes smoked in a lifetime). Many of these molecular lesions are clonal. Such clonal changes can persist for decades after smoking cessation, suggesting a proliferation in cell population. 3p allele loss at several 3p sites appears to be the earliest change followed by 9p (p16 locus), which can be identified in histologically appearing normal epithelium in smokers.

Patients who have had a primary epithelial cancer of the upper aerodigestive tract (head and neck, esophagus, and lungs) have a higher risk of developing a simultaneous or subsequent second primary cancer. It is hypothesized that the epithelial surface of the upper aerodigestive tract may share a common carcinogen exposure and increased risk of cancer development. It is thought that epithelial cancers can arise independently as separate primary cancers following prolonged carcinogen exposure. This effect is called *field cancerization*. Such field effects have also been proposed for breast and colorectal cancers. This hypothesis is testable in that it predicts that if a common carcinogen is involved, second primary cancers will arise from similar but independent events.

To be informative, a molecular marker for determining the independent origin of cancers must have several characteristics. The marker should be associated with the development of the cancer. Alterations in the marker such as mutations should occur early in the development of the cancer. Finally, these mutations should be clonally preserved. The *p53* gene fulfills these criteria for the three most common primary and second primary cancers of the aerodigestive tract: head and neck, lung, and esophagus. Many studies have shown that inactivation of the *p53* gene by mutation or deletion results in cell transformation. Mutations in the *p53* gene occur early in the development of upper aerodigestive tract cancers and are detected frequently in fresh tumor specimens. Mutations in the *p53* gene occur in premalignant lesions from aerodigestive tract cancers. Mutations of the *p53* gene have been frequently detected in early-stage cancers of the head and neck, as well as the lung and esophagus, and the incidence of these mutations does not increase with advancing stage of disease, as would be expected if *p53* mutations were associated with cancer progression. Mutations of the *p53* gene show clonal fidelity

for recurrent cancers and metastases. Differences in *p53* mutations between the primary cancer and second primary cancers would provide evidence of independent origin for these multifocal tumors.

Thirty-one patients with primary cancers of the head and neck and associated second primary cancers were studied by single-strand conformation polymorphism analysis and DNA sequencing. The overall frequencies of *p53* mutations among primary tumors and second primary cancers were 42% (13/31) and 37%(13/35) respectively. Mutations were found in 19 of 52 head and neck squamous cell carcinomas (36%), in 4 of 7 squamous cell carcinomas of the lung (57%), in 2 of 5 adenocarcinomas of the lung, and in 1 of 2 squamous cell carcinomas of the esophagus. Twelve samples had p53 mutations on exon 5, nine on exon 7, and one on exon 8. Six samples had mutations in more than one exon. Twenty-one of 31 patients (68%) had *p53* mutations in one or more specimens. In all 21 cases, the genetic lesions were discordant, such that the presence or location of the mutations differed from those of the second and third primary cancers. In the five patients with *p53* mutations in the initial primary cancer and second primary cancer, the mutations occurred in different regions of the *p53* gene. In the other 16 patients, *a p53* mutation was found in one primary tumor but not in the other. In eight of these cases, a mutation was found in the first primary but not the subsequent primary cancer, and in the other eight cases, a *p53* mutation was not detected in the initial primary cancer but was detected in subsequent primary cancers.

The discordant *p53* mutations in second primary cancers arising in patients with primary epithelial cancer of the upper aerodigestive tract suggest that these cancers arise as independent events. These observations provide the first indication of a molecular basis for field cancerization effects in cancers of the upper aerodigestive tract.

6 Conclusions and Future Prospects

Elimination of tobacco consumption is the most effective way to prevent lung cancer. However, this goal remains elusive. Even if it is achieved, lung cancer will develop well into the twenty-first century in a large number of persons with long exposure histories. Thus, early detection and new therapeutic options are needed to improve the dismal survival for lung cancer. Progress in defining the molecular events involved in the genesis of lung cancer cells has been rapid over the last five years. Potential benefits for patients may be substantial. Identification of persons at high risk for development of lung cancer based on molecular profiles may enable cost-effective implementation of prevention and early detection programs. Conventional therapy has emphasized killing of the last cancer cell by surgical excision or destruction by radiation or chemotherapy. Alteration of oncogene expression by recombinant gene constructs may result in reversal of the transformed phenotype.

Successful therapy and prevention interventions that reverse genetic lesions may be possible. Genetic constructs could specifically inhibit expression of mutant proteins by dominant oncogenes and could replace the function of deleted or mutated tumor suppressor genes if they could be delivered with high efficiency to tumor cells *in vivo*. Viral vectors have the potential for this. The aerodigestive tract is suited to this approach because high concentrations of these relatively nontoxic agents could

be achieved with local installation, thus avoiding the dilutive effects of intravenous injection. If these agents are efficacious, their lack of toxicity may provide a sufficiently high therapeutic index, permitting their use as an adjuvant to surgery to treat patients with earlier stages of cancer, or as preventive therapy for individuals with documented genetic abnormalities in premalignant lesions.

Keywords

Aneuploidy
The presence of an extra or missing chromosome (or chromosomes) in a cell or an organism. Any condition in which the chromosomes are not all present in equal number.

Attenuation
A mechanism by which gene expression in prokaryotes is regulated by the premature termination of transcription.

Autosomal Inheritance
The pattern of inheritance observed for genes located on chromosomes other than the sex chromosomes (chromosomes carrying sex-determining genes).

CentiMorgan (cM)
The measure of the distance between markers on genetic maps based on the average number of crossover events that occur during meiosis. A distance of 1 cM indicates

that 1 recombinant chromosome is present among every 100 chromosomes produced during meiosis.

Codon
The unit of three contiguous nucleotides in mRNA specifying the incorporation of one amino acid in the polypeptide produced by translating that mRNA on the polyribosomes.

Complementation Test
The introduction of two recessive mutations into the same cell but on different chromosomes (a *trans* heterozygote) to determine whether the mutations are both in the same gene or are in two different genes. If the mutations are both in the same gene, the $m1+/+m2$ heterozygote will exhibit a mutant phenotype, whereas if they are in two different genes, the *trans* heterozygote will exhibit the wild-type phenotype.

Crossing-over
A recombination process through which new combinations of genes on specific chromosomes are produced by the breakage and reunion of their DNA molecules.

Dominance
The control of the phenotype of an organism by one allele of a gene correlated with the exclusion of any effect of the other allele.

Epistasis
The interaction of nonalleles. Any condition in which an allele of one gene masks the expression of one or more alleles of a different gene (a nonallele).

Exon
A nucleotide sequence of a gene that corresponds to a sequence that is present in the final processed RNA product of the gene.

Frameshift Mutation
A mutation that alters the codon reading frame of a gene, by either inserting or deleting one or more nucleotide pairs in multiples other than three.

Gain-of-function Mutation
A mutation that produces a gene product with a new function.

Genetic Map
A diagram of a chromosome with distances between markers based on recombination frequencies (centiMorgans).

Heritability
The proportion of the total phenotypic variability present for a trait that results from genetic factors rather than environmental effects.

Independent Assortment
During meiosis, each pair of homologous chromosomes lines up at the metaphase plate independently of every other pair. As a result, the alleles of a gene on one chromosome segregate independently of the alleles of a gene on any nonhomologous chromosome.

Intron
A sequence of nucleotide pairs in a gene that is not present in the mature RNA because it is excised from the primary transcript during processing.

Loss-of-function Mutation
A mutation that impairs or abolishes the expression of a gene or renders its product less active or nonfunctional.

Meiosis
The process by which the chromosome number in reproductive cells is reduced to half the number present in other (somatic) cells of the body. Chromosomes duplicate once and cells duplicate twice to produce haploid gametes.

Mitosis
The separation of the daughter chromatids produced by chromosome replication and the division of the cytoplasm to produce two identical progeny cells.

Mutation
A heritable change in the structure of the genetic material of an organism. When used in the broad sense, mutations include both ''point mutations,'' involving changes in the structure of individual genes, and gross changes in chromosome structure (chromosome aberrations). In the narrow sense, mutations include only ''point mutations.'' The term *mutation* is used to refer to (1) the *process* by which the change occurs and (2) the *result* of the process, the *alteration* in the gene or genetic material.

Nondisjunction
The failure of homologous chromosomes or sister chromatids to separate or disjoin from each other during meiosis or mitosis.

Polyploidy
The presence of three or more copies of each chromosome in a cell or an organism.

Recombination
The generation of new combinations of genes in progeny, which were not present together in either of the parents, either (1) by independent assortment of nonhomologous chromosomes during meiosis or (2) by crossing-over (breakage and exchange of parts) of homologous chromosomes during meiosis or mitosis.

Segregation
The separation of the maternal and paternal chromosomes, and thus the alleles of genes in heterozygotes, from each other during the reductional division of meiosis.

Sex-linked Inheritance
A pattern of inheritance that occurs when the gene controlling a trait is located on a chromosome carrying genes that determine the sex phenotype of the organism.

Suppressor Mutation
A mutation that partially or completely eliminates the phenotypic effect of another mutation.

Transition
A mutation resulting from the replacement of one purine with the other purine and/or one pyrimidine with the other pyrimidine.

Transposable Genetic Element
A DNA unit that can move from one location in a genome to another location or even to a different genome.

Transversion
A mutation resulting from the replacement of a purine with a pyrimidine and/or a pyrimidine with a purine.

The phenotype of a living organism is controlled by its genotype, the summation of its genetic information, acting within the constraints imposed by the environment in which the organism exists. Much of the genetic material of an organism is organized into basic functional units called genes, which specify RNA and/or protein products. Some genes encode one primary gene product, either an RNA molecule or polypeptide. Other genes produce two or more related polypeptides by RNA editing, differential transcript splicing, or the assembly of genes from gene segments during development. The genetic information of all living organisms, whether viruses, bacteria, corn plants, or humans, is stored in the sequence of bases (purines and pyrimidines) or base pairs in the deoxyribonucleic acid (DNA) present in their chromosomes. In some viruses, the genetic information is stored in the sequence of bases in ribonucleic acid (RNA). The genetic information is encoded using a four-letter alphabet: the four bases adenine (A), guanine (G), cytosine (C), and thymine (T). In RNA, uracil (U) replaces the thymine present in DNA. In the double-stranded DNA present in most cellular organisms, adenine and thymine form one base pair (A:T) and guanine and cytosine form a second base pair (G:C).

The genetic material of an organism must carry out three essential functions: (1) the genotypic function, transmission of the genetic information from generation to generation; (2) the phenotypic function, directing the growth and development of

the offspring into mature, reproductive adults; and (3) the evolutionary function, mutation, allowing organisms to evolve in response to changes in the environment. Mutation produces new genetic variability, which provides the raw material for evolution. Recombination of genetic material occurs by the independent assortment of nonhomologous chromosomes and by crossing-over between homologous chromosomes. This recombination provides new combinations of genes and thus new phenotypes on which natural selection acts during the process of evolution.

1
Genetic Information

The genetic information of living organisms is stored in large macromoleules called *nucleic acids*. These nucleic acids are of two types: *DNA* contains the sugar 2′-deoxyribose and *RNA* contains the sugar ribose. In all eukaryotic organisms, the genetic information is stored in giant DNA molecules located in one to many chromosomes, the number depending on the species. In some viruses that contain no DNA, the genetic information is stored in RNA.

1.1
Four-letter Alphabet

The genetic information is stored in nucleic acids using a four-letter alphabet: the four bases *adenine* (A), *guanine* (G), *cytosine* (C), and *thymine* (T) in DNA or *uracil* (U) in RNA. In DNA, which has a double-stranded structure in cellular organisms, the bases are present in pairs: A with T and G with C (Fig. 1). Although a four-letter alphabet may seem too simple to store enough information to produce the vast phenotypic variability observed in living organisms, recall that the Morse code is based on just two symbols – dots and dashes. Moreover, computers perform their amazing feats using a binary code composed of 0s and 1s. Even with just four letters, a vast amount of genetic information can be stored in the large nucleic acids present in living cells. Consider, for example, that one complete copy of the human genome (all the genetic information in one complete set of human chromosomes) contains three-billion (3×10^9) base pairs of DNA. Since the number of different sequences of 4 letters used n at a time is 4^n, one can see that the human genome has the capacity to store a huge amount of information with $n = 3 \times 10^9$.

1.2
The Gene, the Basic Unit of Function

The basic functional unit of genetic information is the *gene*, defined operationally by the complementation test and most commonly specifying the amino acid sequence of one polypeptide chain or the nucleotide sequence of one RNA molecule. Different forms of a given gene are called alleles. The wild-type alleles of a gene are those that exist at relatively high frequencies in natural populations and yield wild-type or ''normal'' phenotypes; they are usually symbolized by a + or a symbol with a + superscript (e.g. w^+ for the allele that yields wild-type red eyes in fruit flies). Alleles of a gene that result in abnormal or non-wild-type phenotypes are called

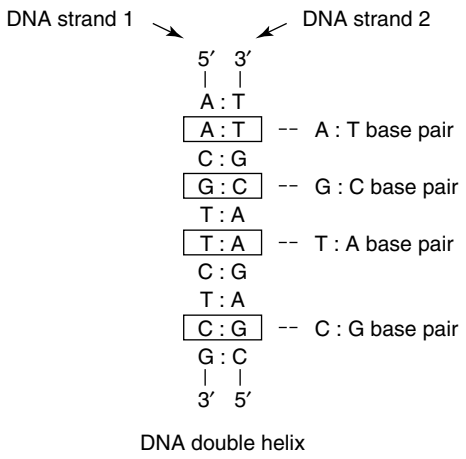

Fig. 1 Two-dimensional view of a segment of double-stranded DNA showing the four base pairs used to store genetic information.

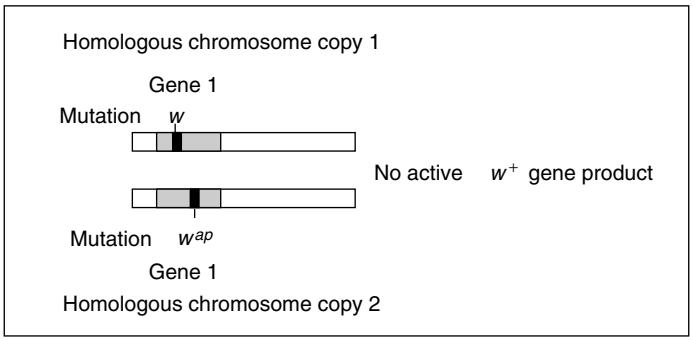
mutant alleles. They are usually symbolized by one to three letters written in italics (e.g. w and w^{ap} for the alleles that cause white and apricot eye color respectively in fruit flies). Many eukaryotes such as corn plants, fruit flies, and humans contain two copies of their genome in most cells, two copies of each of their chromosomes; such eukaryotes are called diploids. Thus, diploid organisms may contain two different alleles of any given gene, in which case they are heterozygous (e.g. w/w^{+}, w^{ap}/w^{+}, w/w^{ap}) or two identical copies of a given gene, in which case they are homozygous (e.g. w^{+}/w^{+}, w/w, w^{ap}/w^{ap}). A w^{ap}/w^{+} heterozygous fruit fly has wild-type red eyes. The w^{+} allele is expressed in this heterozygous fly; w^{+} is thus called the dominant allele. The w^{ap} allele is not expressed in this heterozygous fly; it is said to be recessive because its effect on the phenotype is masked by the w^{+} allele.

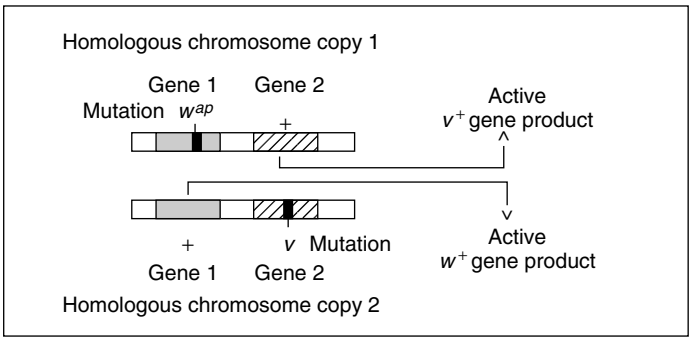
The *complementation test* is performed by producing cells or organisms that contain two recessive mutant genes located on two different chromosomes, that is, *trans* heterozygotes, and by determining whether these cells or organisms have mutant or wild-type phenotypes. If the two mutant genes are allelic, that is, the defects or mutations are in the same gene, the *trans* heterozygote will have a mutant phenotype. If the two mutant genes are not allelic, that is, the mutations are in two different genes, the *trans* heterozygote will have the wild-type phenotype. The rationale behind the complementation test is illustrated in Fig. 2.

1.3 Genes are Located on Chromosomes

One of the important discoveries in biology was that the genetic information of organisms is present in structures called chromosomes, because the transmission of these organelles could be followed during cell division and reproduction. This research culminated in the ''Chromosome Theory of Inheritance,'' which is the core of modern genetics. The DNA molecules that carry the genetic information are packaged into chromosomes with the aid of proteins and RNA molecules. In a eukaryotic cell, the chromosomes are present in a membrane-bounded compartment called the nucleus. The prokaryotic equivalent is the nucleoid, which is not surrounded



(a) Two mutations in the same gene.



(b) Two mutations in two different genes.

Fig. 2 Illustration of the complementation test used to operationally define the gene, the basic unit of function of genetic material. The operation is to place the two recessive mutations in question in the same cell or cells of a multicellular organism on two separate chromosomes, that is, to construct a *trans* heterozygote, and to determine whether this cell or organism has a mutant or a wild-type phenotype. If the phenotype is mutant, the two mutations are in the same gene; this is illustrated for the *w* (white eyes) and w^{ap} (apricot eyes) mutations of *Drosophila* in (a). If the phenotype of the *trans* heterozygote is wild type, the two mutations are in two different genes and the two mutations are said to complement each other. Complementation between the w^{ap} and *v* (vermilion eye color) mutations of *Drosophila* is illustrated in (b); note that active (wild-type) products of both genes (w^+ and v^+) are present in the *trans* heterozygote shown in (b) – thus, the wild-type phenotype.

by a membrane. An important function of the chromosomes is to ensure the proper distribution of the genetic material to daughter cells during cell division.

Each chromosome contains a single large DNA molecule packaged in a matrix of RNA and protein. The DNA is highly compacted by coiling and supercoiling. If the DNA in a single human chromosome were uncoiled so that it was a perfectly linear molecule, it would measure between 2.5 and 8.5 cm in length. During cell division, this DNA molecule is present in a chromosome that is only about 0.5 μm in diameter and 3 to 10 μm in length. Eukaryotic chromosomes have several distinct structural features that are visible under the light microscope (Fig. 3). After replication, each chromosome is composed of

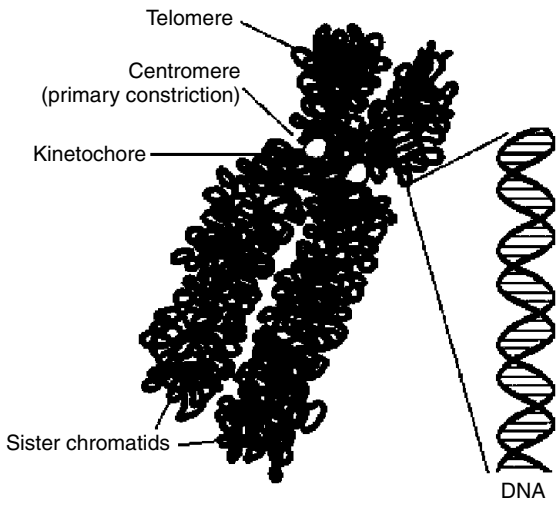


Fig. 3 The structure of a highly condensed replicated eukaryotic chromosome. (Reproduced from Snustad, D.P., Simmons, M.J., *Principles of Genetics*, 3rd edition, Copyright © 2003 by John Wiley & Sons, Inc., Hoboken, NJ, USA. This material is used by permission of John Wiley & Sons, Inc.)

two sister chromatids joined together at a constriction called the centromere The kinetochore, a protein structure present in each centromere, plays an important role in the separation of daughter chromosomes during cell division. The position of the centromere varies from the middle to the end of the chromosome. The ends of the chromosomes are called telomeres; they contain unique molecular structures that enhance chromosome stability.

1.4 Autosomal and Sex-linked Inheritance

In many eukaryotes, sex phenotype is controlled by key regulatory genes that are present on chromosomes that are not present as morphologically identical or nearly identical pairs of homologous chromosomes. In humans, for example, an important male-determining gene, *SRY* (for *s*ex-determining *r*egion of the *Y*), which encodes the testis-determining factor (TDF), is located on a small chromosome called the *Y chromosome*. This chromosome is normally present only in males (there are rare exceptions). During reproductive divisions, it pairs with a much larger chromosome called the *X chromosome*, which is present in two copies in females. The X and Y chromosomes share common terminal regions, allowing them to pair during meiosis. This chromosomal mechanism of sex determination is called the XX-XY mechanism. It occurs in humans and other mammals, the fruit fly *Drosophila melanogaster*, and a number of other species. In some species, the Y chromosome is completely absent and males have one less chromosome than females (the XX-XO mechanism of sex determination). The X and Y chromosomes are referred to as sex chromosomes, and all the other chromosomes (present in morphologically identical pairs) are called *autosomes*. Humans, for example, contain the 2 sex chromosomes and 44 autosomes (22 homologous pairs).

The human Y chromosome plays a major role in sex determination; however, it is small and contains very few genes that affect other traits. In contrast, the X chromosome is large and contains

a large number of important genes. The absence of an X chromosome is lethal in humans. Given that females contain two X chromosomes and males contain one X and one Y, whereas both females and males contain two copies of each autosome, traits controlled by genes located on sex chromosomes will exhibit different patterns of inheritance than traits controlled by genes on autosomes

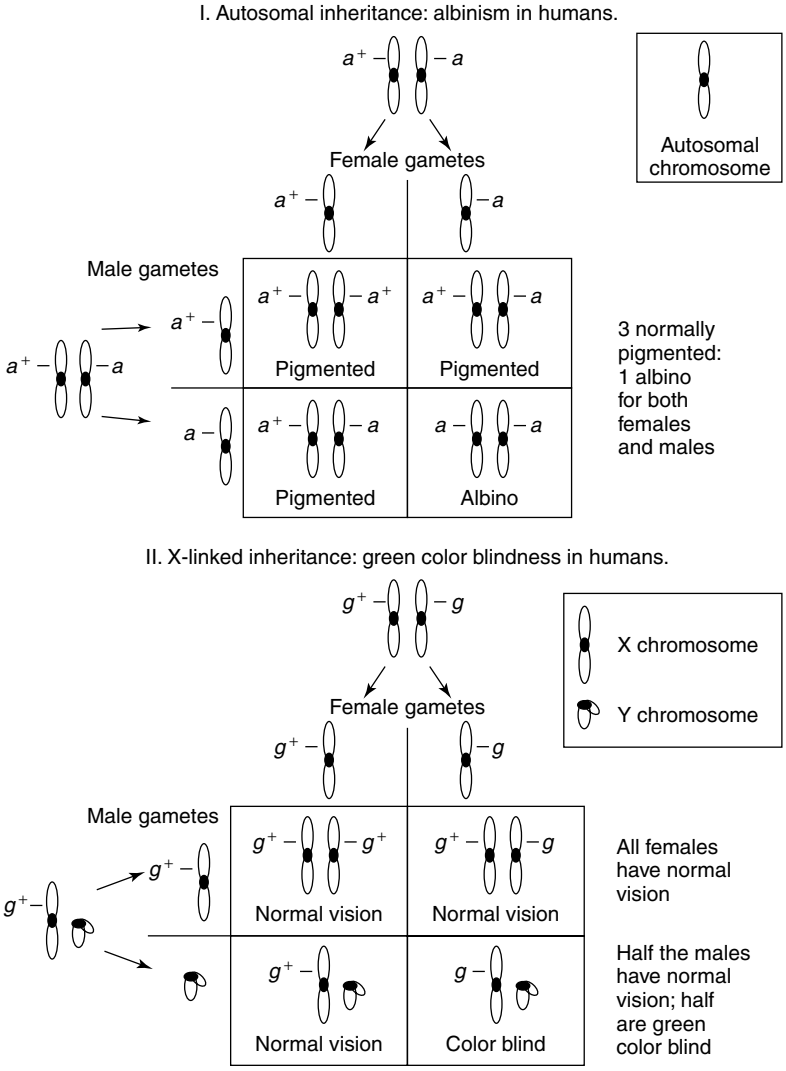

Fig. 4 Autosomal versus sex-linked (X-linked) inheritance. (a) Autosomal inheritance: the expected results are shown for a mating between two individuals who are both heterozygous for a recessive allele causing albinism. (b) X-linked inheritance: the predicted results are shown for a mating between a woman who is heterozygous for a recessive allele causing green color blindness and a male with normal vision.

(Fig. 4). In humans, albinism is caused by a recessive mutation in any of several autosomal genes, whereas green color blindness is caused by a recessive mutant allele of a gene on the X chromosome.

Note that the X chromosome of a male is always passed to his daughters, because the offspring would be male if it received a Y chromosome. Given that the X chromosome contains many essential genes, a son has to get an X chromosome from his mother. Because a male has only one X chromosome, recessive traits such as color blindness and hemophilia are expressed much more frequently in males. Males are *hemizygous* (''half that of a zygote'') for X-linked genes; if a recessive X-linked allele is present, it will be expressed. Females contain two X chromosomes; they will have to be homozygous for a recessive X-linked allele to express the trait. Thus, if an X-linked recessive allele is present in a population with a frequency of q, and if there is random mating in the population with respect to this trait, the recessive trait will occur with a frequency of q in males and a frequency of q^2 in females. To express the trait, females will have to obtain one X chromosome carrying the mutant allele from the mother via the egg and a second X chromosome carrying the mutant allele from the father through the sperm. These are independent events, and the probability that two independent events will both occur is equal to the product of the probabilities of the individual events ($q \times q = q^2$). Thus, it is easy to see why males express X-linked traits more frequently than females. In contrast, traits controlled by genes located on autosomes are usually expressed with equal frequency in the two sexes.

Females who receive a recessive X-linked mutant allele from their father often do not express it because they receive the wild-type allele from their mother. However, they will transmit the mutant allele to half of their hemizygous sons, who will express the trait. These heterozygous women are referred to as ''carriers'' of the trait; they carry the mutation, but do not show any effect of its presence.

Females have two copies of every gene on the X chromosome; males have only one. In humans and other mammals, this difference in gene dosage is corrected by inactivating one of the two X chromosomes in each cell in females. This inactivation occurs at random, so half of a woman's cells express her maternal X chromosome and the other half express her paternal X chromosome. Women are, therefore, mosaics for the expression of genes on their X chromosomes. The inactivation occurs early during development and results in a highly condensed chromosome that is visible under the light microscope as a densely staining ''Barr body.'' The inactivated X chromosome undergoes reactivation during oogenesis so that all eggs contain active X chromosomes.

Sex is determined by many different mechanisms in other species. In birds, males contain two identical sex chromosomes and females contain two distinct sex chromosomes. In ants, bees, wasps, and other Hymenoptera, males have only one copy of each chromosome, whereas females carry two copies. Males are ''haploid''; they develop from unfertilized eggs. Females are diploid, developing from fertilized eggs as in most other eukaryotes. In still other species, special sex chromosomes are not present, and environmental factors play key roles in sex determination. Thus, when considering sex-linked inheritance, one must not extrapolate from humans and fruit flies to other species.

1.5 Mendelian versus Quantitative Traits

Mendel studied pea plants that differed in specific phenotypic characteristics such as red flowers versus white flowers, tall versus dwarf, round seeds versus wrinkled seeds, and so on. As a result, he was able to classify the progeny of his crosses into distinct phenotypic classes and calculate the frequency of each class. Such traits are now referred to as *Mendelian traits*, because they yield the predicted monohybrid, dihybrid, and so on, segregation ratios in genetic crosses. Many other traits show continuous variation such that the progeny of crosses cannot be placed into discreet phenotypic classes. In humans, height and weight exhibit continuous variation from the shortest or smallest individual to the tallest or heaviest individual. The inheritance of such traits must be studied using quantitative measurements; therefore, the traits are commonly called *quantitative traits*. The genes that control quantitative traits are no different than the genes that control Mendelian traits. The difference is that quantitative traits are influenced by a large number of genes; they are multifactorial, being influenced by many factors, both genetic and environmental. Geneticists have developed statistical tools that can be used to estimate the number of genes affecting a trait, the proportion of the phenotypic variability that is genetic (caused by genes), and the proportion that is environmental (due to environmental factors). For a given trait, the proportion of the total phenotypic variability that is caused by genetic factors is the trait's *heritability*. Estimates of heritability for traits such as yield in grains and growth rate in domestic livestock have played an important role in the enhanced agricultural productivity realized in developed countries of the world during the last half century.

1.6 Genomics: Analyses of Entire Genomes

The science of genetics began with Mendel's monohybrid, dihybrid, and trihybrid crosses in garden peas at the monastery in Brünn (now Brno in the Czech Republic). Most of the early studies focused on the effects of one or a few genes. As the science matured, slot-blot and dot-blot hybridization technology allowed geneticists to simultaneously examine the expression of many genes. These blot hybridization procedures culminated in the development of microarray technologies that facilitated studies of hundreds to thousands of genes at once. Then, in 1995, the complete nucleotide sequence of the genome of the bacterium *Haemophilus influenzae* was published. The nucleotide sequences of many other bacteria were subsequently reported, along with the sequence of the genome of the yeast *Saccharomyces cerevisiae*. The nearly complete sequences of several model systems – the worm *Caenorhabditis elegans*, the fruit fly *D. melanogaster*, and the plant *Arabidopsis thaliana* – followed. Then, in early 2001, two drafts of the sequence of the human genome were published, followed in 2002 by drafts of the sequences of the genomes of two subspecies of rice.

Sophisticated computer programs were developed that allowed scientists to scan these sequences and identify open reading frames (ORFs), sequences with no "stop" signals that would prevent the synthesis of a protein product in at least one of the three reading frames.

These tools could be used to predict the presence and location of all the genes in a genome with reasonable accuracy. Gene-specific hybridization probes were then synthesized on the basis of the gene sequences and were used to prepare whole-genome microarrays. New technologies were used to array thousands of oligonucleotide hybridization probes on silicon wafers only a few square centimeters in size. These microarrays, commonly called "gene chips," allow geneticists to simultaneously study the expression of all the genes in an organism. All these developments led to a new subdiscipline of genetics – *genomics* – focused on the structure and function of entire genomes.

2
DNA Replication: The Genotypic Function

The genetic information of an organism must be transmitted from cell to cell during development and from generation to generation during reproduction. This transfer of genes from parents to offspring – the *genotypic function* – occurs by the accurate replication of DNA, that is, by the production of two progeny DNA molecules that are identical to the parental DNA molecule.

2.1
Semiconservative Replication

When Watson and Crick worked out the double-helix structure of DNA in 1953, they recognized that the complementary nature of the two strands – A paired with T and G paired with C – might play an important role in its replication. If the two strands of a parental double helix of DNA separated, the base sequence of each parental strand could serve as a template for the synthesis of a new complementary strand, producing two identical progeny double helices. This process is called *semiconservative replication* because the parental double helix is half conserved, each parental single strand remaining intact (Fig. 5). Meselson and Stahl documented the semiconservative replication of DNA in *E. coli* in 1958.

2.2
Proofreading

DNA replication is amazingly accurate with only about one error for every billion bases incorporated. This accuracy is necessary to keep the mutation load at a tolerable level, especially in large genomes such as those of mammals, which contain 3×10^9 nucleotide pairs. On the basis

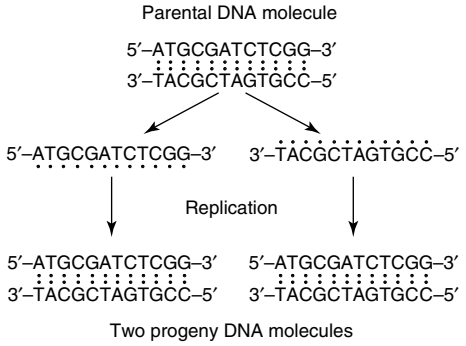

Fig. 5 Semiconservative DNA replication. The single strands of the parental double helix are separated and each strand serves as a template for the synthesis of a complementary strand of DNA. The process results in the production of two progeny double helices that are identical to the parental double helix.

of the dynamic structures of the four nucleotides in DNA, the observed fidelity of DNA replication is much higher than expected. The thermodynamic changes in nucleotides that allow the formation of hydrogen-bonded base pairs other than A : T and G : C predict error rates of 10^{-5} to 10^{-4} or 1 error per 10 000 to 100 000 incorporated nucleotides. The predicted error rate of 10 000 times the observed error rate raises the question of how this high fidelity of DNA replication is achieved. The answer is that a mechanism for *proofreading* the nascent DNA chain as it is being synthesized has evolved in living organisms.

DNA proofreading involves scanning the termini of nascent DNA chains for errors and correcting them before continuing chain extension. This process is carried out by a $3' \rightarrow 5'$ exonuclease activity that is built into DNA polymerases. When a template–primer DNA has a terminal mismatch (an unpaired or incorrectly paired base or sequence of bases at the 3′ end of the primer), the $3' \rightarrow 5'$ exonuclease activity of the DNA polymerase clips off the unpaired base or bases (Fig. 6). When an appropriately base-paired terminus is produced, the $5' \rightarrow 3'$ polymerase activity of the enzyme begins resynthesis by adding nucleotides to the 3′ end of the primer strand. In mutant organisms that lack the proofreading activity of polymerases, the mutation rate is orders of magnitude higher than that in organisms with normal proofreading activity. Thus, proofreading is an important component of the semiconservative replication of DNA.

2.3 The Complex Replisome

DNA replication is complex, requiring the participation of a large number of proteins, and only a few of the most

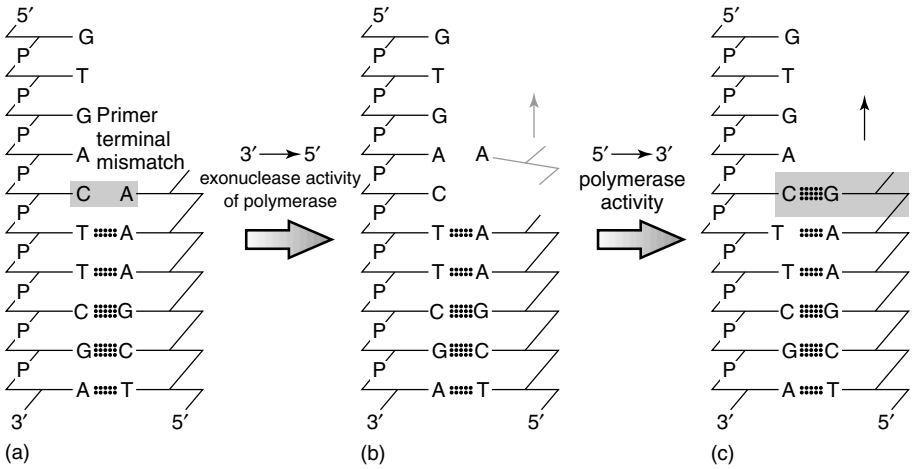

Fig. 6 Proofreading by the $3' \rightarrow 5'$ exonuclease activity of DNA polymerases during DNA replication. If DNA polymerase is presented with a template and primer containing a 3′ primer terminal mismatch (a), the $3' \rightarrow 5'$ exonuclease activity will cleave off the mismatched terminal nucleotide (b). Then, given a correctly base-paired primer terminus, DNA polymerase will catalyze a $5' \rightarrow 3'$ covalent extension of the primer strand (c). (Reproduced from Snustad, D.P., Simmons, M.J., *Principles of Genetics*, 3rd edition, Copyright © 2003 by John Wiley & Sons, Inc., Hoboken, NJ, USA. This material is used by permission of John Wiley & Sons, Inc.)

important features of the process will be considered here. A nucleic acid chain has a chemical polarity based on the phosphodiester bonds that link the 5′ and 3′ carbons of adjacent nucleotides; that is, each chain will have a 5′ carbon at one end and a 3′ carbon at the other end. The complementary strands of a DNA double helix have opposite chemical polarity, with one strand $5' \rightarrow 3'$ and the other strand $3' \rightarrow 5'$, moving unidirectionally along the molecule. Because both nascent strands are extended as a replication fork moves along a parental double helix, one strand is extended at the macromolecular level in the $5' \rightarrow 3'$ direction and the other strand in the $3' \rightarrow 5'$ direction. However, DNA polymerases only catalyze $5' \rightarrow 3'$ synthesis; at the molecular level, all synthesis is $5' \rightarrow 3'$.

DNA synthesis is continuous on the progeny strand that is being extended in the overall $5' \rightarrow 3'$ direction but is discontinuous on the strand growing in the overall $3' \rightarrow 5'$ direction (Fig. 7). Discontinuous replication occurs by the synthesis of short DNA strands (1000 to 2000 nucleotides long in bacteria and 100 to 200 nucleotides long in eukaryotes). The short DNA strands are called ''Okazaki fragments'' after the scientists who discovered them.

The Okazaki fragments are initiated by short RNA primers synthesized by DNA primase. The RNA primers are subsequently replaced by DNA sequences by the combined $5' \rightarrow 3'$ exonuclease and polymerase activities of a repair DNA polymerase (DNA polymerase I in *Escherichia coli*), and the Okazaki fragments are then joined by DNA ligase.

DNA replication involves many additional enzymes and other proteins. Replication requires that the two strands of a parental DNA molecule be separated during the synthesis of new complementary strands. Given that each gyre, or turn, of DNA is about 10 nucleotide pairs long, a DNA molecule must be rotated 360° once for every 10 replicated base pairs. In *E. coli*, DNA replicates at a rate of about 30 000 nucleotides per minute. Thus, a replicating DNA molecule must spin at 3000 revolutions per minute to facilitate the unwinding of the parental DNA strands. The unwinding process is catalyzed by enzymes called DNA helicases. The unwound strands are prevented from re-pairing by becoming coated with single-strand DNA-binding proteins (SSB proteins). The binding of SSB proteins to single-stranded DNA is cooperative; that is, the binding of the first SSB monomer stimulates the binding of additional monomers at contiguous sites on the DNA chain. Because of the cooperativity of SSB protein binding, an entire single-stranded region of DNA is rapidly coated with SSB protein.

Bacterial chromosomes contain circular molecules of DNA. With DNA spinning at 3000 revolutions per minute during unwinding of the parental strands, a swivel or axis of rotation is required to prevent tangles of supercoils from forming ahead of the replication fork. The required axes of rotation are provided by enzymes called DNA topoisomerases. The topoisomerases catalyze transient breaks in DNA molecules but use covalent linkages to themselves to hold on to the cleaved molecules, allowing subsequent reformation of the cleaved bonds. The transient single-strand break produced by the activity of topoisomerase I provides an axis of rotation that allows the segments of DNA on opposite sides of the break to spin independently, with the phosphodiester bond in the intact strand serving as

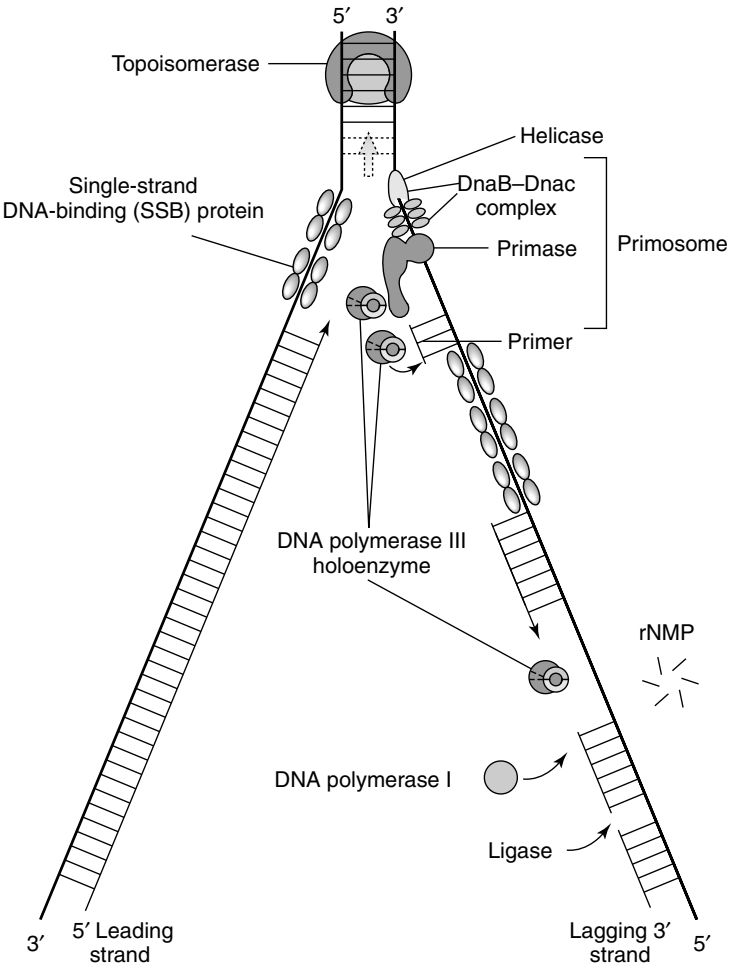

Fig. 7 Diagram of a replication fork in *E. coli* showing the major components of the replisome (rNMP, ribonucleoside monophosphates). (Reproduced from Snustad, D.P., Simmons, M.J., *Principles of Genetics*, 3rd edition, Copyright © 2003 by John Wiley & Sons, Inc., Hoboken, NJ, USA. This material is used by permission of John Wiley & Sons, Inc.)

a swivel. Thus, during DNA replication, only a short segment of DNA in front of the replication fork needs to spin – the segment up to the closest transient nick by topoisomerase I. Another *E. coli* topoisomerase called DNA gyrase is also required for DNA replication. DNA gyrase uses energy from ATP and introduces and removes negative (left-handed) supercoils in DNA.

DNA replication also requires a number of different proteins that are involved in the initiation or priming of synthesis at specific origins of replication. These proteins bind to specific nucleotide sequences at the origin and

induce localized strand separation or ''bubbles'' in which the synthesis of nascent strands begins. All the enzymes and DNA-binding proteins involved in replication assemble into a *replisome* at each replication fork and act in concert as the fork moves along the parental DNA molecule (Fig. 7).

3
Gene Expression: The Phenotypic Function

The genetic information controls the growth and development of the organism, be it a virus, a bacterium, a plant, or an animal. This genetic information must be expressed accurately – the *phenotypic function* – both spatially and temporally to produce the appropriate three-dimensional form of the organism. In multicellular organisms, the genetic information must control the growth and differentiation of the organism from the single-celled zygote to the mature adult. To accomplish this phenotypic function, each gene of an organism must be expressed at the proper time and in the proper cells during development. The initial steps in the pathways of gene expression, transcription and translation, are quite well elucidated; these steps are illustrated for the expression of the human β-globin gene in Fig. 8. In contrast,

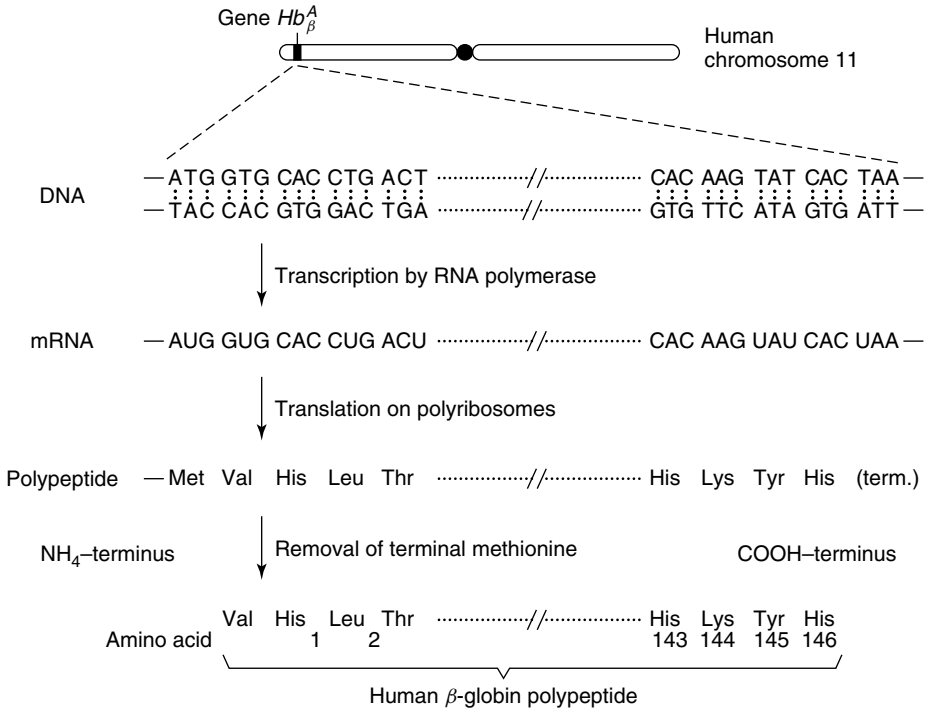

Fig. 8 Schematic diagram showing the first steps in the expression of the human gene (Hb^A_β) encoding β-globin: transcription, translation, and the proteolytic removal of the amino-terminal methionine residue from the primary translation product. For simplicity, only the terminal portions of the coding sequence and the polypeptide product are shown.

we are just beginning to understand morphogenesis at the cell, tissue, and organ levels.

3.1 Colinearity between Gene and Polypeptide

The genetic information is stored in linear sequences of nucleotide pairs in DNA (or nucleotides in RNA, in some cases). Transcription and translation convert this genetic information into *colinear* sequences of amino acids in polypeptides, which function as the key intermediaries in the genetic control of the phenotype. The first three base pairs of the coding sequence of a gene specify the first amino acid of the polypeptide, the next three base pairs (four to six) specify the second amino acid, and so on, in a colinear fashion (Fig. 9). Although the coding regions of most of the genes in higher eukaryotes are interrupted by noncoding sequences called introns, their presence does not invalidate the concept of colinearity. The presence of introns in genes simply means that there is no direct correlation in physical distances between the positions of base-pair coding triplets in a gene and the positions of amino acids in the polypeptide specified by that gene. The coding sequences and the polypeptides that they encode are still colinear.

3.2 Transcription

The first step in gene expression, *transcription*, involves converting genetic information stored in the form of base pairs in double-stranded DNA into the sequence of bases in a single-stranded molecule of messenger RNA (mRNA). This process is catalyzed by enzymes called RNA polymerases and occurs when one strand of the DNA is used as a template to synthesize a complementary strand of RNA using the same base-pairing rules as for DNA replication, except that uracil is incorporated into RNA at positions where thymine would be present in DNA (see Fig. 8, top). Like replication, transcription is a complex process involving numerous proteins called transcription factors. Transcription is initiated at specific sequences within regions called promoters located adjacent to the gene. Transcription initiation factors bind to these sequences and induce localized unwinding of the DNA molecule. RNA synthesis occurs within these locally unwound ''transcription bubbles'' as RNA polymerase moves along the DNA template strand. Chain extension occurs in the $5' \rightarrow 3'$ direction by a mechanism very similar to DNA synthesis. The termination of transcription also occurs at specific nucleotide sequences,

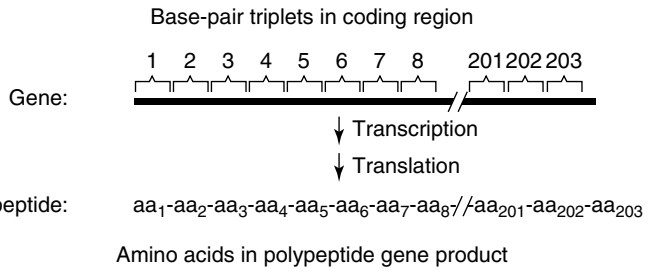

Fig. 9 Colinearity between the base-pair triplets in the coding region of a gene and the amino acid sequence in the polypeptide product of the gene.

sometimes with the aid of other termination proteins.

3.3 Introns and RNA Splicing

Most of the genes of eukaryotes are interrupted by sequences that are not represented in the mature RNA products of these genes. These sequences are called *introns* (for *in*tervening sequences). The coding sequences and other sequences that are present in the final RNA products of these interrupted genes are called *exons* (for *ex*pressed sequences). The structure of a typical eukaryotic gene is shown in Fig. 10.

Not all eukaryotic genes contain introns, so they are not required for expression. When present, the number of introns per gene varies from one to over 50, and the intron size varies from about 50 nucleotide pairs to thousands of nucleotide pairs. The human *DMD* gene, which is responsible for Duchenne muscular dystropy when nonfunctional, is one of the largest known. The *DMD* gene contains 78 introns and is over 2.5-million nucleotide pairs in length. Rare genes of Archaea and of a few viruses of prokaryotes also contain introns. In the case of these ''split'' genes, the primary transcript contains the entire sequence of the gene and the intron sequences are excised during RNA processing.

For genes that encode proteins, the splicing mechanism must be precise; it must join exon sequences with accuracy to the single nucleotide to assure that codons in exons distal to introns are read correctly. Accuracy to this degree would seem to require precise splicing signals, presumably nucleotide sequences within introns and

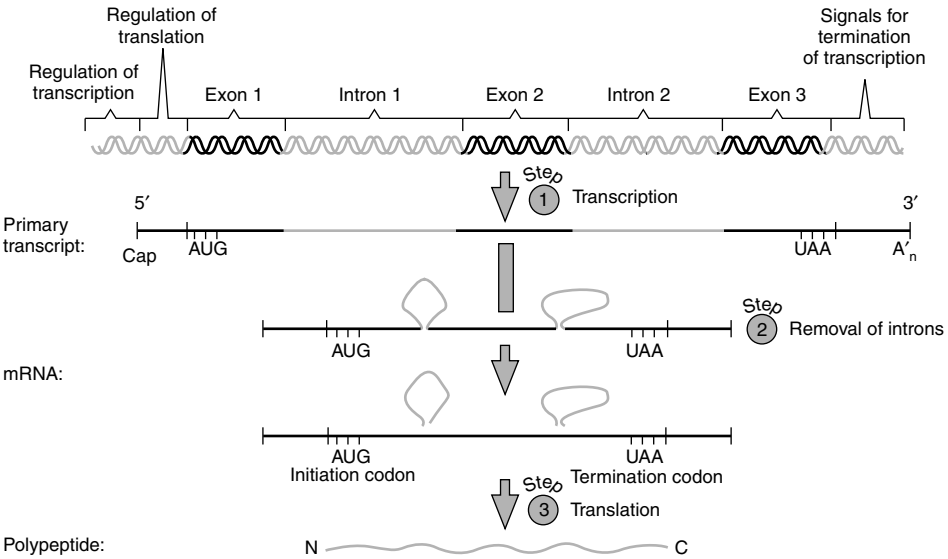

Fig. 10 Structure of a typical eukaryotic gene. Note that the intron sequences are present in the primary transcript but are removed during nuclear processing to produce the mature mRNA prior to its export to the cytoplasm for translation. (Reproduced from Snustad, D.P., Simmons, M.J., *Principles of Genetics*, 3rd edition, Copyright © 2003 by John Wiley & Sons, Inc., Hoboken, NJ, USA. This material is used by permission of John Wiley & Sons, Inc.)

at the exon–intron junctions. However, in the primary transcripts of nuclear genes, the only completely conserved sequences of different introns are the dinucleotide sequences at the ends of introns. In primary transcripts, all introns begin with GU and end with AG. For nuclear genes, there is also one somewhat conserved sequence located about 30 nucleotides from the 3′ splice site. The introns of genes of mitochondria and chloroplasts also contain conserved sequences, but they are different from those of nuclear genes.

There are three major classes of intron excision from RNA transcripts. The introns of tRNA precursors are excised by precise endonucleolytic cleavage and ligation reactions catalyzed by special splicing endonuclease and ligase activities. The introns of some rRNA precursors are removed autocatalytically in a unique reaction mediated by the RNA molecule itself. No protein enzymatic activity is involved. The introns of nuclear pre-mRNA transcripts are excised in two-step reactions carried out by complex ribonucleoprotein particles called spliceosomes. For details about the splicing mechanisms, see [Lewin (2000) or Alberts et al. (2002)].

3.4 RNA Editing

According to the central dogma of molecular biology, genetic information flows from DNA to RNA to protein during gene expression. Normally, the genetic information is not altered in the mRNA intermediary. However, the discovery of *RNA editing* has shown that exceptions do occur. RNA editing processes alter the information content of gene transcripts in two ways: (1) by changing the structures of individual bases and (2) by inserting or deleting uridine monophosphate residues. The first type of RNA editing, which results in the substitution of one base for another base, is rare. This type of editing was discovered in studies of the apolipoprotein-B *(apoB)* genes and mRNAs in rabbits and humans. Apolipoproteins are blood proteins that transport certain types of fat molecules in the circulatory system. In the liver, the *apoB* mRNA encodes a large protein 4563 amino acids long. In the intestine, the *apoB* mRNA directs the synthesis of a protein only 2153 amino acids long. Here, a C residue in the pre-mRNA is converted to a U, generating an internal UAA translation–termination codon, which results in the truncated apolipoprotein. The C → U conversion is catalyzed by a sequence-specific RNA-binding protein with an activity that removes amino groups from cytosine residues. In some transcripts present in plant mitochondria, most of the Cs are converted to U residues.

A second, more complex type of RNA editing occurs in the mitochondria of trypanosomes. In this case, uridine monophosphate residues are inserted (occasionally deleted) into gene transcripts, causing major changes in the polypeptides specified by the mRNA molecules. This RNA editing process is mediated by guide RNAs transcribed from distinct mitochondrial genes. The guide RNAs contain sequences that are partially complementary to the pre-mRNAs to be edited. Pairing between the guide RNAs and the pre-mRNAs results in gaps with unpaired A residues in the guide RNAs. The guide RNAs serve as templates for editing, as Us are inserted in the gaps in pre-mRNA molecules opposite the As in the guide RNAs. In some cases, two or more different guide RNAs participate in the editing of a single pre-mRNA. For some unknown reason, RNA editing plays a major role in

the expression of genes in the mitochondria of trypanosomes and plants.

3.5 Translation

During *translation*, the sequence of bases in the mRNA molecule is converted (''translated'') into the specified sequence of amino acids in the polypeptide gene product according to the rules of the genetic code (Fig. 8, center). Each amino acid is specified by one or more codons, and each codon contains three nucleotides. Of the 64 possible nucleotide triplets, 61 specify amino acids and 3 specify polypeptide chain termination. Translation occurs on ribosomes, which are complex macromolecular structures located in the cytoplasm (Fig. 11). Translation involves three types of RNA, all of which are transcribed from DNA templates (chromosomal genes). In addition to mRNAs, 3 to 5 RNA molecules (rRNA molecules) are present as part of the structure of each ribosome, and 40 to 60 RNA molecules (tRNA molecules) function as adaptors by mediating the incorporation of the proper amino acids into polypeptides in response to specific nucleotide sequences in mRNAs. The amino acids are attached to the correct tRNA molecules by a set of

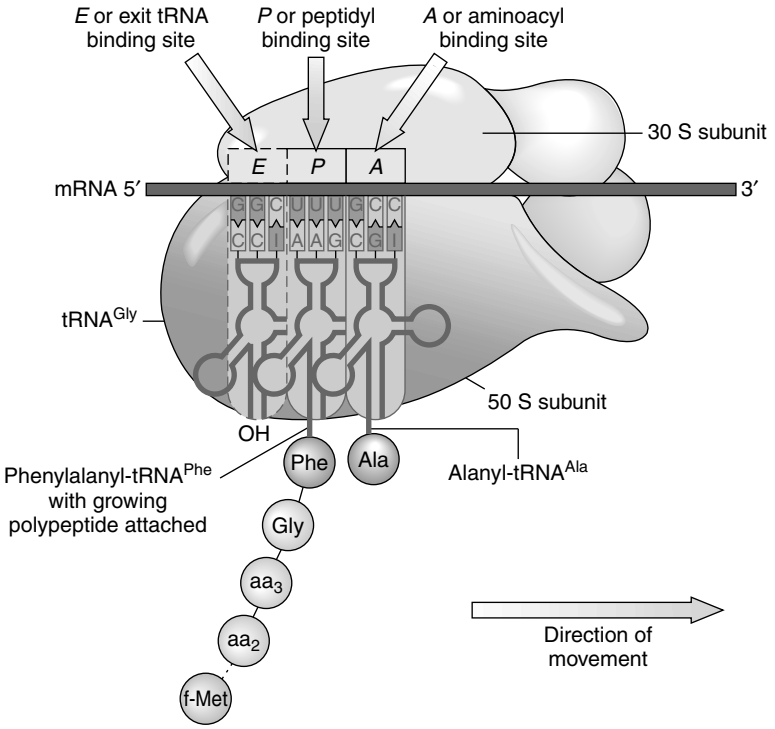

Fig. 11 Diagram of a bacterial 70S ribosome showing the three tRNA binding sites and the base pairing between the codons of the mRNA and the anticodons of the tRNAs. (Reproduced from Snustad, D.P., Simmons, M.J., *Principles of Genetics*, 3rd edition, Copyright © 2003 by John Wiley & Sons, Inc., Hoboken, NJ, USA. This material is used by permission of John Wiley & Sons, Inc.)

activating enzymes called aminoacyl tRNA synthetases. The tRNA molecules contain nucleotide triplets called anticodons, which base pair with the codons in mRNA during the translation process.

The ribosomes may be thought of as workbenches, complete with machines and tools needed to make a polypeptide. They are nonspecific in the sense that they can synthesize any polypeptide (any amino acid sequence) encoded by a particular mRNA molecule, even an mRNA from a different species. Each mRNA molecule is simultaneously translated by several ribosomes, resulting in the formation of polyribosomes. The translation of the sequence of nucleotides in an mRNA molecule into the sequence of amino acids in its polypeptide product can be divided into three stages: (1) polypeptide chain initiation; (2) chain elongation; and (3) chain termination.

In *E. coli*, the translation initiation process involves the 30S subunit of the ribosome, a special initiator tRNA, an mRNA molecule, three soluble protein initiation factors IF-1, IF-2, and IF-3, and one molecule of GTP. In the first stage of the initiation of translation, a free 30S subunit interacts with an mRNA molecule and the initiation factors. The 50S subunit joins the complex to form the 70S ribosome in the final step of the initiation process. The addition of the 50S ribosomal subunit to the complex positions the initiator tRNA, methionyl-$tRNA_f^{Met}$, in the peptidyl (*P*) site of the ribosome with the anticodon of the tRNA aligned with the AUG initiation codon of the mRNA. Methionyl-$tRNA_f^{Met}$ is the only aminoacyl tRNA that can enter the *P* site directly, without first passing through the aminoacyl (*A*) site. With the initiator AUG positioned in the *P* site, the second codon of the mRNA is in register with the *A* site, dictating the aminoacyl tRNA binding specificity at that site and setting the stage for the second phase in polypeptide synthesis, chain elongation.

The process of polypeptide chain elongation is basically the same in both prokaryotes and eukaryotes. The addition of each amino acid to the growing polypeptide occurs in three steps: (1) binding of an aminoacyl tRNA to the *A* site of the ribosome; (2) transfer of the growing polypeptide chain from the tRNA in the *P* site to the tRNA in the *A* site by the formation of a new peptide bond; and (3) translocation of the ribosome along the mRNA to position the next codon in the *A* site. During step 3, the nascent polypeptide-tRNA and the uncharged tRNA are translocated from the *A* and *P* sites to the *P* and *E* sites respectively. These three steps are repeated in a cyclic manner throughout the elongation process. Polypeptide chain elongation proceeds rapidly. In *E. coli*, all three steps required for the addition of one amino acid to the growing polypeptide chain to occur in about 0.05 s. Thus, the synthesis of a polypeptide containing 300 amino acids takes only about 15 s.

Polypeptide chain elongation undergoes termination when any of the three chain-termination codons (UAA, UAG, or UGA) enters the *A* site on the ribosome. These three stop codons are recognized by soluble proteins called release factors (RFs). In *E. coli*, there are two release factors, RF-1 and RF-2. RF-1 recognizes termination codons UAA and UAG; RF-2 recognizes UAA and UGA. In eukaryotes, a single release factor (eRF) recognizes all three termination codons. Termination is completed by the release of the mRNA molecule from the ribosome and the dissociation of the ribosome into its subunits.

3.6 Inteins

Occasionally, the primary translation product of a gene contains one or more short amino acid sequences, called *inteins*, that excise themselves from the nascent polypeptide. Inteins occur in both eukaryotic and prokaryotic polypeptides; one of the first inteins discovered is in the RecA protein (required for recombination) in *Mycobacterium tuberculosis*, the bacterium that causes tuberculosis. The ability to carry out intein excision is a function of the structure of the primary translation product and is thus encoded in the gene just like any other amino acid sequence.

3.7 Some Complex Gene/Protein Relationships

As discussed in Section 3.3, most eukaryotic genes are split into expressed sequences (exons) and intervening sequences (introns). In some cases, transcripts of split genes may undergo several different types of splicing, making the relationships between genes and proteins more complex than the usual one gene–one polypeptide. In other cases, expressed genes are assembled from "gene pieces" during the development of the specialized cells in which they are expressed.

When the transcripts of an interrupted gene undergo alternate pathways of transcript splicing, different exons are joined to produce a related set of mRNAs that encode a family of closely related polypeptides. These interrelated polypeptides are called *protein isoforms*. Alternate splicing pathways are often tissue-specific, producing related proteins that carry out similar, but not necessarily identical, functions in different types of cells. The mammalian tropomyosin genes produce complex families of protein isoforms. Tropomyosins regulate muscle contraction in animals. One mouse tropomyosin gene produces at least 10 different polypeptides by alternate pathways of transcript splicing. Genes of this type do not fit the one gene–one polypeptide concept very well. Such genes can be defined as DNA sequences that are single units of transcription and encode a set of protein isoforms.

Genetic information is not always organized into genes of the type described in Section 1.2. In a few cases, genes are assembled from a storehouse of gene segments during the development of an organism. The immune system of vertebrate animals depends on the synthesis of proteins called antibodies to provide protection against infections by viruses, bacteria, toxins, and other foreign substances. Each antibody contains four polypeptides, two identical heavy chains and two identical light chains. The light chains are of two types: kappa and lambda. Each antibody chain contains a variable region, which exhibits extensive diversity from antibody to antibody, and a constant region, which is largely the same in all antibodies. In germ-line chromosomes, the DNA sequences encoding these antibody chains are present in gene segments, and the gene segments are joined together to produce genes during the differentiation of the antibody-producing B-lymphocytes from progenitor cells. The B-lymphocytes subsequently differentiate into antibody-secreting plasma cells.

This process of *gene assembly during development* is illustrated in Fig. 12. A kappa light chain gene is assembled from three gene segments V_k (V for variable region), J_k (J for joining segment), and

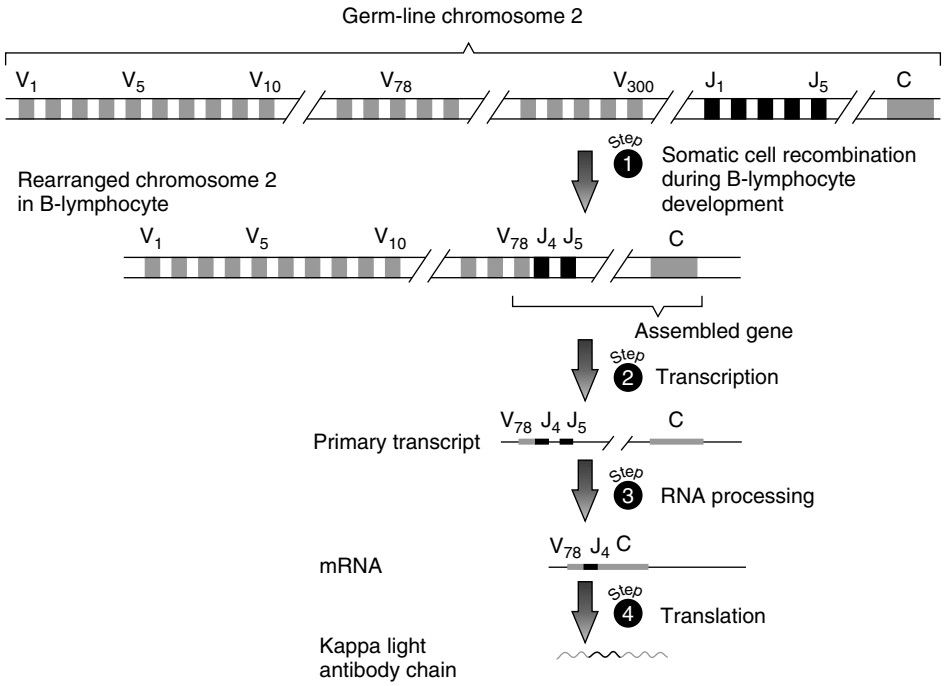

Fig. 12 Assembly of a gene encoding an antibody kappa light chain from gene segments during B-lymphocyte differentiation in humans. (Reproduced from Snustad, D.P., Simmons, M.J., *Principles of Genetics*, 3rd edition, Copyright © 2003 by John Wiley & Sons, Inc., Hoboken, NJ, USA. This material is used by permission of John Wiley & Sons, Inc.)

C_k (C for constant region) during B-lymphocyte development. Together, the V_k and J_k gene segments encode the variable region of the kappa light chain, whereas the C_k gene segment encodes the constant region. No functional V_k–J_k–C_k kappa light chain gene is present in any human germ-line chromosome. Instead, human chromosome 2 contains a cluster of about 300 V_k gene segments, another cluster of 5 J_k gene segments, and a single C_k gene segment (Fig. 12). During the differentiation of each B-lymphocyte, recombination joins one of the V_k gene segments to one of the J_k gene segments. Any J_k segments remaining between the newly formed V_k–J_k exon and the C_k gene segment become part of an intron that is removed during the processing of the primary transcript. Similar somatic recombination events are involved in the assembly of the genes encoding antibody heavy chains, lambda light chains, and T-lymphocyte receptor proteins.

3.8 Pathways of Gene Expression are Often Complex

The pathway through which a gene exerts its effect on the phenotype of the organism is often long and complex, especially in multicellular eukaryotes (Fig. 13). Pathways of gene action frequently involve protein–protein and other macromolecular interactions, cell–cell interactions and

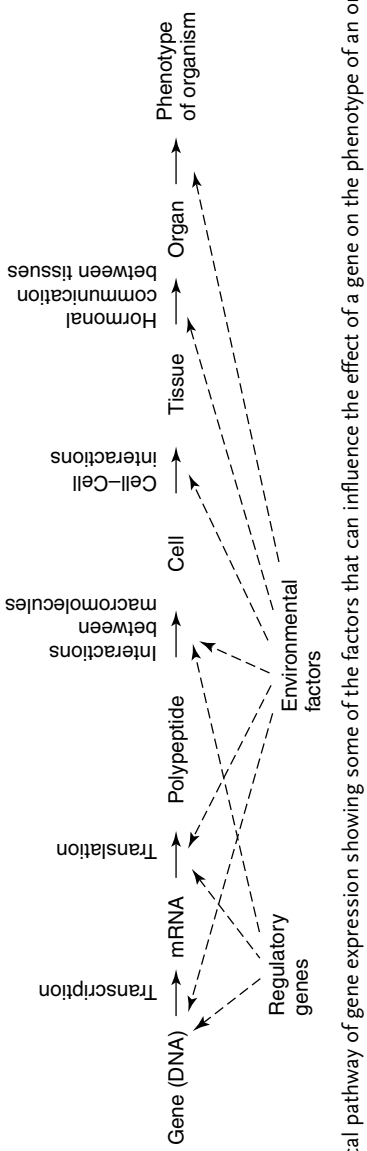

Fig. 13 A typical pathway of gene expression showing some of the factors that can influence the effect of a gene on the phenotype of an organism.

intercellular communication by hormones and other signal molecules, tissue and organ interactions, and restrictions imposed by environmental factors. Note that, although not shown here, each gene also has an effect on the phenotype of the population in which the organism lives (population genetics) and ultimately on the phenotype of the biosphere (ecological genetics).

3.9 Pleiotropy and Epistasis

Sometimes, a single gene influences many aspects of an organism's phenotype. When this occurs, the gene is said to be pleiotropic. The mutant gene that causes sickle-cell anemia in humans provides a classic example of *pleiotropy*. This inherited disorder results from a mutation in the β-globin gene that changes the sixth amino acid from a glutamic acid in the wild-type β-globin to a valine in the sickle-cell polypeptide. This amino acid substitution alters the conformation of the polypeptide, causing aggregation of hemoglobin molecules and the development of grossly deformed red blood cells. These sickle-shaped cells have reduced capacity to transport oxygen and, therefore, cause the anemia. However, the sickle cell allele not only causes hemolytic anemia in the homozygous state but also has many other effects such as enlarged spleen, impaired growth, recurrent pain, and increased susceptibility to microbial and viral infections. Perhaps the allele's most unexpected pleiotropic effect is the enhanced resistance to *Paramecium falciparum* malaria, which it provides when present in the heterozygous state.

When two or more genes influence a trait, an allele of one of them may mask the effects of alleles of the other gene on the phenotype. When an allele has such an overriding effect, it is said to be epistatic to the other genes. The occurrence of such interactions between different genes (nonalleles) is called *epistasis*. There are many examples of epistasis. In *Drosophila*, a recessive mutation in the cinnabar gene causes the eyes of the fly to be bright red. A recessive mutation in another gene results in white eyes. Flies that are homozygous for both these mutations have white eyes. The white mutation is, therefore, epistatic to the cinnabar mutation. In humans and other mammals, recessive mutant alleles that cause albinism are usually epistatic to other genes affecting eye and hair color.

3.10 Penetrance and Expressivity

Sometimes, a mutant gene can be present in an organism without having any effect on its phenotype. Such a gene is said to exhibit *incomplete penetrance*. In humans, polydactyly, the presence of extra fingers and toes, provides an example of incomplete penetrance. This condition is caused by a dominant mutation that results in polydactyly in some, but not all, individuals who are known to carry it. Penetrance is measured by determining what proportion of the individuals who carry a gene exhibit the trait made possible by its presence. Incomplete penetrance can be a serious problem in pedigree analysis, sometimes resulting in the assignment of incorrect genotypes.

In other cases, the presence of a gene may result in a range of phenotypic effects from mild to severe. Such a gene is said to exhibit *variable expressivity*. The dominant Lobe eye mutation in *Drosophila* provides an example of variable expressivity; its phenotypic effect varies from tiny compound eyes, through a

full range of intermediates, to large, lobulated eyes.

3.11 Intragenic Complementation

The results of complementation tests are usually unambiguous when recessive mutations that result in the synthesis of no gene product, partial gene products, or totally defective gene products are used – for example, deletions of segments of genes or polypeptide chain–terminating mutations. When mutations that cause amino acid substitutions are used, the results are sometimes ambiguous because of the occurrence of a phenomenon called *intragenic complementation*.

The functional forms of some proteins are dimers or higher multimers consisting of two or more polypeptides. These polypeptides may be either the products of a single gene or the products of two or more different genes. When the active form of the protein contains two or more homologous polypeptides, intragenic complementation sometimes occurs. *Inter*genic complementation (discussed in Section 1.2) and *intra*genic complementation are distinct phenomena.

As a simple example of intragenic complementation, consider an enzyme that functions as a homodimer, that is, a protein containing two copies of a specific gene product. An organism that is heterozygous for two different mutations in the gene will produce some dimers that contain the two different mutant polypeptides. We call these heterodimers. Such heterodimers may have partial or complete (wild-type) function; when this occurs, intragenic complementation has occurred. In such cases, the *trans* heterozygote has a wild-type phenotype or a phenotype intermediate between mutant and wild type. Why such heteromultimers should be active when the two corresponding homomultimers are inactive is not clear. Apparently, the wild-type sequence of amino acids in the nonmutant segment of one mutant polypeptide somehow compensates for the mutant segment of the polypeptide encoded by the second mutant allele, and vice versa. In the case of noncomplementing mutations in a gene encoding a multimeric protein, the heteromultimers are nonfunctional, just like the mutant homomultimers.

3.12 Intergenic Noncomplementation

In some cases, mutations known to be located in two different genes fail to complement each other. This phenomenon is called *intergenic noncomplementation*, and it has become a powerful tool for identifying genes encoding products that interact. If two different polypeptides are part of a macromolecular complex, mutations in the two genes encoding them may not complement each other. The presence of mutant polypeptides in the complex may render the entire complex nonfunctional, even if wild-type products of both genes are present. Thus, the occurrence of intergenic noncomplementation provides evidence that the two gene products interact in some way. Intergenic noncomplementation is allele-specific; not all mutations in the genes involved will exhibit the phenomenon.

3.13 Regulation of Gene Expression

In all organisms, gene expression is highly regulated so that energy is used to synthesize gene products only when those products are needed for the growth and

differentiation of the organism. In higher eukaryotes, only a small proportion of the genes in any genome are expressed in a given cell type. Thus, gene expression is highly programmed such that genes needed to make neurons are only turned on in developing nerve cells, genes needed to make red blood cells are only expressed in progenitors of erythrocytes, and so on. Most microorganisms exhibit a striking ability to regulate the expression of specific genes in response to environmental signals. The expression of particular genes is turned on when the products of these genes are needed for growth. Their expression is turned off when the gene products are no longer needed. Gene expression is regulated at several different levels: transcription, mRNA processing, mRNA turnover, translation, and posttranslation (Fig. 14). However, the regulatory mechanisms with the largest effects on phenotype act at the level of transcription.

Most regulatory mechanisms fit into two general categories: (1) the rapid turn-on or turn-off of gene expression in response to environmental changes (especially important in microorganisms) and (2) preprogrammed circuits of gene expression (important in all organisms).

Certain "housekeeping" gene products – tRNA molecules, rRNA molecules, ribosomal proteins, and the like – are essential components of all living cells. These genes are continually being expressed in most cells; they are referred to as *constitutive genes*. Other gene products are needed only in the presence of specific metabolites. They are not expressed in the absence of the metabolite but are turned on when the metabolite is present. This process is called *induction*. Genes whose expression is regulated in this manner are called *inducible genes*; their products, if enzymes, are called *inducible enzymes*. Enzymes that are involved in catabolic pathways are often inducible. Other genes are turned on and they synthesize their gene products unless the metabolite synthesized by those products is present in the environment. Then, they are turned off. This process is called *repression*, and genes that are regulated in this manner are called *repressible genes*. Enzymes that are components of anabolic pathways are often repressible. Both induction and repression occur at the level of transcription.

The regulation of gene expression, induction or repression, can be accomplished by both positive and negative control mechanisms. Both mechanisms involve the participation of *regulator genes* – genes whose products regulate the expression of other genes. In *positive control mechanisms*, the product of the regulator gene functions by turning on the expression of one or more genes, whereas in *negative control mechanisms*, the product of the regulator gene is involved in shutting off the expression of genes. Positive and negative regulation mechanisms can both mediate either inducible or repressible gene expression.

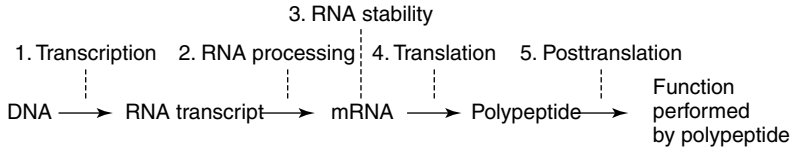

Fig. 14 Pathway of gene expression showing five stages at which gene expression is regulated.

A given gene is expressed when RNA polymerase binds to its promoter and synthesizes an RNA transcript that contains the coding region of the gene. The product of the regulator gene acts by binding to a site called the regulator protein binding site (*RBS*) adjacent to the promoter of the structural gene (or genes). When the product of the regulator gene is bound to *RBS*, transcription of the structural gene(s) is turned on in a positive control system or is turned off in a negative control system. The regulator gene products are called *activators* in positive control systems and *repressors* in negative control systems. Whether a regulator protein can bind to the *RBS* depends on the presence or absence of *effector molecules* in the cell. The effectors are usually small molecules such as amino acids, sugars, and similar metabolites. The effector molecules involved in induction of gene expression are called *inducers*; those involved in repression of gene expression are called *corepressors*.

The effector molecules (inducers and corepressors) bind to regulator gene products (activators and repressors) and cause changes in the three-dimensional structures of these proteins. Such changes in protein conformation are called *allosteric transitions*. In the case of activators and repressors, the allosteric transitions alter their ability to bind to regulator protein binding sites adjacent to the genes that they control.

In microorganisms, *operons* – negatively and coordinately regulated units of gene expression – play important regulatory roles. Each operon contains one to many structural genes, adjacent to promoter and operator sequences. The operator is the binding site for the repressor (inducible system) or the repressor/corepressor complex (repressible system). When the repressor or repressor/corepressor complex is bound to the operator, it prevents RNA polymerase from transcribing the structural genes of the operon. When the repressor is not bound to the operator, RNA polymerase binds to the promoter and transcribes the genes in the operon. Another important regulatory mechanism in microorganisms – attenuation – occurs by the control of premature termination of transcription.

Regulation of gene expression in eukaryotes usually involves the binding of several proteins called *transcription factors* to upstream promoters and to regulatory sequences called *enhancers* and *silencers*, which can be located either upstream of, downstream from, or within the genes that they regulate. As the names suggest, enhancers and silencers increase and decrease, respectively, the levels of gene expression.

3.14 RNA-mediated Gene Silencing

RNA-mediated gene silencing (*RMGS*) was first studied in plants where it was called *posttranscriptional gene silencing* (*PTGS*). Similar RNA-induced gene silencing processes were subsequently discovered in animals and fungi and were called *RNA interference* (*RNAi*) and *quelling*, respectively. RMGS is triggered by the presence of double-stranded RNA (dsRNA). The dsRNA may be composed of two complementary or partially complementary single strands or a self-complementary RNA molecule containing complementary regions such that it folds back on itself and forms a hairpin-like structure. The dsRNAs are degraded to 21- to 22-nucleotide-long dsRNA fragments called *small interfering RNAs* (*siRNAs*) by the

ribonuclease ''Dicer.'' The siRNA fragments subsequently become associated with an endonuclease-containing complex called RISC for ''RNAi silencing complex.'' This complex binds to and degrades mRNA molecules that contain sequences complementary to the sequence of the siRNAs. RMGS requires several other gene products, including an RNA-dependent RNA polymerase, an RNA helicase, and the proteins in RISC. Additional components of the RMGS pathways are currently being investigated in both plants and animals.

RMGS is believed to be a defense mechanism protecting the host organism from viral infections, runaway transposons, and other invading DNAs and dsRNAs. In addition, the recent identification of families of naturally occurring *microRNAs* with self-complementary sequences that form ''hairpin'' structures and give rise to siRNA-like fragments suggests that RMGS may play important roles in regulating growth and development and other important natural processes. Finally, the mechanisms by which PTGS, RNAi, and quelling occur in various species are probably similar but not necessarily identical. Indeed, there are probably multiple pathways by which RMGS can occur, even within a species.

In addition to their normal biological function(s), RMGS has become an important tool for reverse genetic analyses, allowing researchers to shut off genes in a controlled manner. In *C. elegans*, RNAi was used to systematically ''knock out'' the expression of each of the genes on chromosomes I and III respectively. In plants, chimeric gene cassettes that direct the synthesis of hairpin RNAs and induce PTGS have proven to be effective in producing gene knockouts. Thus, RMGS is an important tool in the field of functional genomics.

4 Mutation: The Evolutionary Function

Although the genetic information must be transmitted from generation to generation with considerable accuracy, it is not static, but it undergoes occasional change or *mutation – the evolutionary function* – to produce new genetic variability that provides the raw material for ongoing evolution. The new variant genes produced by mutation are called mutant alleles and often result in abnormal or mutant phenotypes. When used in the narrow sense, mutation refers only to changes in the structures of individual genes. However, in the broad sense, mutation refers to any heritable change in the genetic material and includes gross changes in chromosome structure or chromosome aberrations. In addition, the word mutation refers not only to the change in the genetic material but also to the process during which the change occurs.

4.1 Dominance, Partial Dominance, and Codominance

When mutations occur producing new mutant alleles, these alleles can exhibit a range of interactions with the original or wild-type allele. The phenomenon of interactions between various alleles of a given gene is called *dominance*. If an organism that is heterozygous for a wild-type allele and a mutant allele has the same phenotype as an organism that is homozygous for the mutant allele, the mutant allele is *dominant* and the wild-type allele is *recessive*. If the heterozygote has the wild-type phenotype, the reverse is true: the mutant allele is recessive and the wild-type allele is dominant. If the phenotype of the heterozygote is intermediate between the

phenotypes of the respective homozygotes, the mutant allele exhibits *partial dominance* (sometimes called semidominance) or no dominance (if the phenotype is precisely intermediate to the phenotypes of the two homozygotes). If both alleles produce their phenotypic effects in heterozygotes, the alleles are said to be *codominant*. Humans with the AB blood type (genotype $I^A I^B$), for example, have both type A antigens and type B antigens on their red blood cells. Thus, the I^A and I^B alleles are codominant.

4.2 Transitions, Transversions, and Frameshift Mutations

Point mutations within individual genes may be either base-pair substitutions or the insertion or deletion of one or a few contiguous base pairs. Base-pair substitutions usually result in the substitution of a single amino acid in the mutant polypeptide gene product. Base-pair substitutions are of two types: *transitions* and *transversions*. Transitions occur when one purine is substituted for the other purine and the corresponding pyrimidine for pyrimidine substitutions take place in the complementary strand of DNA. Transversions involve purine for pyrimidine and pyrimidine for purine substitutions. Of the 12 different base-pair substitutions, 4 are transitions and 8 are transversions (Fig. 15).

Sickle-cell anemia in humans is the result of a single base-pair substitution, a transversion, in the adult β-globin gene. This disorder occurs in individuals who are homozygous for the altered β-globin gene. This single base-pair substitution in the Hb_β^S gene changes the sixth amino acid of the β-globin polypeptide from glutamic acid in Hb_β^A homozygotes to valine in Hb_β^S homozygotes (Fig. 16). This one amino acid change in the human β-globin chain results in sickle-shaped red blood cells and in sickle-cell anemia in individuals homozygous for the Hb_β^S allele. Thus, a single base-pair substitution in DNA can have a very large effect on the phenotype of the organism harboring the mutation.

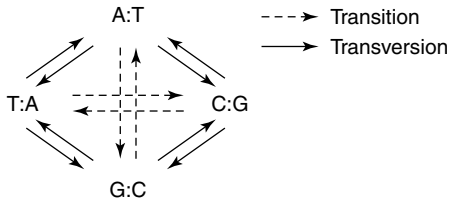

Fig. 15 Base-pair substitutions in DNA.

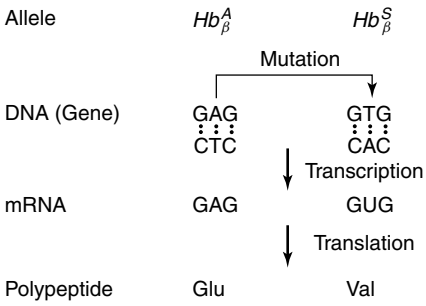

Fig. 16 The mutational origin of sickle-cell anemia in humans.

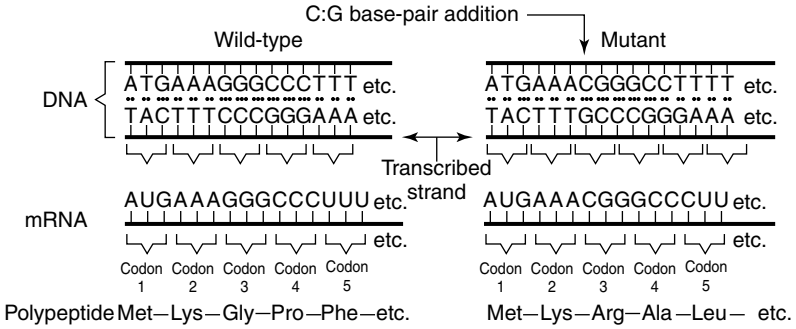

Insertions or deletions of one or two base pairs alter the reading frame of the gene distal to the site of the mutation.

Fig. 17 The effect of a frameshift mutation, in this case a C:G base-pair insertion. (Reproduced from Snustad, D.P., Simmons, M.J., *Principles of Genetics*, 3rd edition, Copyright © 2003 by John Wiley & Sons, Inc., Hoboken, NJ, USA. This material is used by permission of John Wiley & Sons, Inc.)

The insertion or deletion of one or two base pairs within the coding sequence of a gene alters the codon reading frame in the mRNA (Fig. 17); thus, such mutations are referred to as *frameshift mutations*. Frameshift mutations usually result in totally nonfunctional gene products.

4.3 Gain-of-function and Loss-of-function Mutations

Mutations may also be classified on the basis of their effect on the function of the altered gene products. Mutations that diminish or eliminate the activity of a gene product are called *loss-of-function* mutations. Most recessive mutations are simple loss-of-function mutations. However, some loss-of-function mutations are dominant (for example, when the mutant product interferes with the activity of the wild-type gene product) or partially dominant (for example, when the threshold level of gene product activity requires two functional copies of the gene). Many dominant mutations are *gain-of-function* mutations; they produce mutant alleles that encode products with new functions. Some gain-of-function mutations result in the synthesis of altered polypeptides with novel activity. Others result in the synthesis of the gene products in cells or tissues in which they are not normally synthesized.

4.4 Suppressor and Enhancer Mutations

Two classes of mutations have proven to be especially valuable to researchers investigating the genetic control of a specific biological process. Given an organism with a mutant phenotype caused by a mutation in one gene that affects a trait, researchers can often identify other genes affecting the trait by screening for *suppressor mutations* or *enhancer mutations*. Suppressor mutations partially or completely cancel the effect of the original mutation, whereas enhancer mutations cause the mutant phenotype to be more extreme. In both cases, the mutations usually occur in genes that encode products involved in the same pathway or process, acting either upstream of

or downstream from the product of the gene altered by the original mutation.

4.5 Chromosome Aberrations

There are four types of gross chromosome rearrangements or *chromosome aberrations*: duplications, deletions, inversions, and translocations. A *duplication* is the occurrence of a segment of a chromosome in two or more copies per genome. A *deletion* or *deficiency* results from the loss of a segment of a chromosome. An *inversion* occurs when a segment of a chromosome is turned end-for-end relative to its orientation in a normal chromosome. A *translocation* results when a segment of a chromosome is broken off and becomes reattached to another chromosome. All four types of chromosome aberrations can have major effects on the phenotype and fertility of an organism.

4.6 Polyploidy

Numerical changes in chromosome number are referred to as changes in *ploidy*. *Euploidy* involves variations in the number of copies of the genome or complete sets of chromosomes in a cell or an organism. *Aneuploidy* occurs when there are missing or extra copies of one or a few chromosomes.

All the other sections of this article have focussed on the genetics of *diploid* ($2n$) organisms such as humans and fruit flies. Diploid organisms contain two copies of the genome in their germline cells and most, but not all, somatic cells. However, not all organisms are diploids; some animals, for example, certain fish and salamanders, and many plants are *polyploid*, that is, contain more than two copies of the genome. Many important crop species are polyploids: seedless watermelons are triploid ($3n$), cotton is a tetraploid ($4n$), bread wheat is a hexaploid ($6n$), and strawberries are octaploids ($8n$). Polyploidy has played an important role in the evolution of plants.

4.7 Nondisjunction and Aneuploidy

During mitosis, each chromosome duplicates and the two daughter chromosomes separate, with one going to each progeny cell. Similarly, during meiosis, the two homologous chromosomes separate during the first division, and then the two daughter chromosomes (previously chromatids) move to separate cells during the second division. The result of a normal mitosis or meiosis is that all the progeny cells receive complete sets of chromosomes. Occasionally, however, homologous chromosomes and daughter chromosomes fail to separate or disjoin properly during mitosis or meiosis. The failure of chromosomes to separate properly during mitosis or meiosis is called *nondisjunction*. Nondisjunction produces cells or gametes with extra or missing chromosomes; it is the primary cause of aneuploidy.

Whereas euploidy is not detrimental *per se*, aneuploidy is, especially in animals. In humans, aneuploidy is almost always lethal. Excluding individuals who are mosaics containing cells with two or more different karyotypes (chromosome sets), only seven types of aneuploidy exist in humans. *Monosomy* occurs when one member of a pair of chromosomes is missing; *trisomy* occurs when three copies of a chromosome are present. In humans, only one monosomic condition, Turner syndrome (X0, the presence of a

single X chromosome), is viable. Monosomy for any of the autosomes is lethal. Five trisomic conditions are viable in humans: Klinefelter syndrome (XXY), Down syndrome (trisomy 21), Patau syndrome (trisomy 13), Edward syndrome (trisomy 18), triplo-X (XXX), and XYY. Trisomy for any of the other autosomes is lethal. The message is clear; the genes in our genome have evolved as a coadapted set of instructions. Each of the genes in our genome must be expressed at the proper time and in the proper place during development to produce a normal human being. Anything that disrupts the delicate balance of preprogrammed gene expression required for normal development is highly deleterious.

4.8 Expanding Trinucleotide Repeats in Humans

Another class of mutations – *expanding trinucleotide repeats* – are responsible for several inherited neurological diseases in humans. Tandemly repeated sequences of one to six nucleotide pairs are known as simple tandem repeats. Such repeats are dispersed throughout genomes, including the human genome. Repeats of three nucleotide pairs, trinucleotide repeats, are known to increase in copy number and give rise to mutant alleles. In humans, several trinucleotides undergo such increases in copy number. Expanded CGG trinucleotide repeats on the X chromosome are responsible for fragile X syndrome, the most common form of inherited mental retardation. Normal X chromosomes contain from 6 to about 50 copies of the CGG repeat at the *FRAXA* site. Mutant X chromosomes contain up to 1000 copies of the tandem CGG repeat at this site. CAG and CTG trinucleotide repeats are involved in several inherited neurological diseases, including Huntington disease, myotonic dystrophy, Kennedy disease, dentatorubral pallidoluysian atrophy, Machado Joseph disease, and spinocerebellar ataxia. In all these neurological disorders, the severity of the disease is correlated with trinucleotide copy number – the higher the copy number, the more severe the disease symptoms. In addition, the expanded trinucleotides associated with these diseases are unstable in somatic cells and between generations. This instability gives rise to the phenomenon of ''anticipation,'' which is the increasing severity of the disease or earlier age of onset that occurs in successive generations as the trinucleotide copy number increases.

5 Recombination: New Combinations of Genes to be Acted on by Natural or Artificial Selection

Mutation produces new genetic variability, but the resulting mutant genes must be placed in new combinations with previously existing genes so that natural selection (or artificial selection in the case of plant and animal breeding) can preserve those combinations that produce the organisms best adapted to specific environments (or desired by the breeder). These new combinations are produced by recombination mechanisms that are essential to the process of evolution.

5.1 Segregation

In an organism that is heterozygous for two different alleles of a gene, such as tall (*D*) and dwarf (*d*) in Mendel's peas, the two alleles segregate from each other during the formation of gametes. The

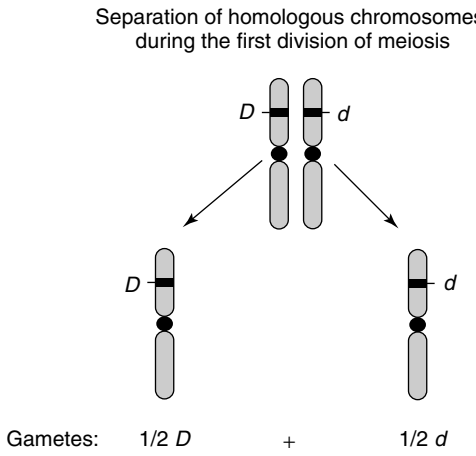

Fig. 18 Segregation of alleles during the first division of meiosis.

biological basis of this segregation is the pairing and subsequent separation of homologous chromosomes during the first (reductional) division of meiosis (Fig. 18).

5.2 Independent Assortment

New combinations of genes on nonhomologous chromosomes are produced by the independent assortment of chromosomes during the first division of meiosis (Fig. 19). Consider a cross between two double homozygotes, for example, *AA BB* and *aa bb*, where genes *A* and *B* are on different chromosomes. The F_1 progeny (F_1 for first filial generation) will be double heterozygotes (*Aa Bb*). Half of the gametes produced by F_1 progeny will have the same combination of alleles as the

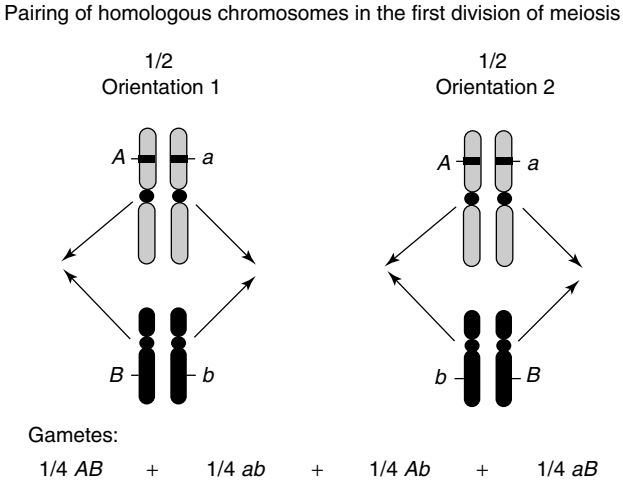

Fig. 19 The generation of new combinations of genes by the independent assortment of nonhomologous chromosomes during meiosis.

parents (1/4 AB + 1/4 ab). The other half will have new (recombinant) combinations of the alleles (1/4 Ab and 1/4 aB). The recombination of pairs of alleles on different chromosomes is the result of the *independent assortment* of the homologous chromosomes during the first division of meiosis. Each pair of homologous chromosomes lines up at the metaphase plate independently of every other pair. Both maternal chromosomes may be on the same side of the metaphase plate, with the two paternal chromosomes on the other side, or one maternal chromosome may be on the same side of the metaphase plate as the paternal member of the other chromosome pair, and vice versa. The result is that the segregation of the alleles of a gene on one chromosome occurs independently of the segregation of the alleles of any gene on a nonhomologous chromosome.

5.3 Linkage, Crossing-over, and Genetic Maps of Chromosomes

Because organisms contain far more genes than chromosomes, not all pairs of alleles can assort independently of one another. Humans, for example, contain 23 pairs of chromosomes and approximately 35 000 genes. Thus, each chromosome contains many genes. Genes that are relatively close together on the same chromosome tend to stay together; if less than 50% of the gametes produced during meiosis in a double heterozygote have a recombinant combination of the alleles (see Section 5.2), the genes are said to be *linked*. New combinations of the alleles of genes on the same chromosome are produced by *crossing-over* (breakage and exchange of parts) between homologous chromosomes during meiosis and mitosis (Fig. 20). During an early stage (prophase) of meiosis, the homologous chromosomes pair (a process called *synapsis*) side by side. This pairing facilitates crossing over, which occurs by cutting DNA strands with enzymes called endonucleases, exchanging single strands of DNA from homologous chromosomes with the aid of recombination proteins, and rejoining the strands of DNA in new combinations with the assistance of DNA polymerases and DNA ligases. DNA ligases seal single-strand breaks in DNA molecules; they play important roles in replication, recombination, and DNA repair processes.

The frequency of crossing over and thus the frequency at which recombinant combinations of linked genes occur are approximately proportional to the distance between genes on the chromosome.

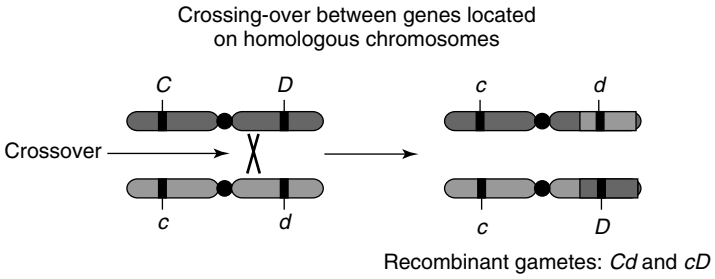

Fig. 20 The generation of new combinations of genes by crossing-over between genes located on homologous chromosomes during meiosis or mitosis.

This relationship is used to prepare *genetic maps* of chromosomes, which show the linear order and the relative positions of genes on a chromosome. Crosses are performed between organisms with different combinations of the alleles of genes on a specific chromosome, and the frequency of gametes carrying recombinant combinations of the alleles of the genes is determined. As an interesting historical sidelight, this genetic mapping procedure was developed by Alfred H. Sturtevant while he was still an undergraduate working in Thomas Hunt Morgan's laboratory at Columbia University in 1911. When genes are relatively far apart on a chromosome, multiple crossovers may occur between them. When two crossovers (or an even number) occur between two genes, the second cancels out the first, and all the resulting gametes will have parental combinations of the alleles of the genes. Thus, map distances are based on the average number of crossovers between genes. One map unit (one centiMorgan, cM) is the genetic distance in which an average of 1 chromatid out of a 100 will have undergone a crossover event. For distances less than 20 map units, the map distance is approximately equal to the proportion of recombinant chromosomes produced in percent, or 1 cM equals the distance yielding 1% recombinant gametes. Figure 21 contains an abbreviated genetic map of the X chromosome in *D. melanogaster*.

5.4 Transposable Genetic Elements

Living organisms contain remarkable DNA elements that can jump from one site in the genome to another site. These mobile elements are called *transposable genetic elements* or *transposons*. The insertion of one of these transposons into a gene will often render the gene nonfunctional, producing a mutant allele. Indeed, the wrinkled allele that Mendel studied in the garden pea was caused by the insertion of a transposable element.

Transposable elements are present in both prokaryotes and eukaryotes and

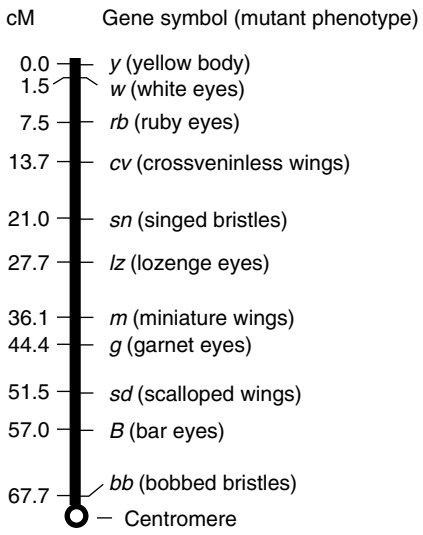

Fig. 21 Abbreviated genetic map of the X chromosome of *Drosophila*. Distances are given in centiMorgans (approximately equal to the percentage of recombinant chromosomes).

exhibit a variety of structures and mechanisms of transposition. However, most of them can be grouped into one of three classes. *Cut-and-paste transposons* move by excision from one site and insertion into another site. *Replicative transposons* move during replication, with the old copy remaining at the initial site and the nascent copy being inserted at a new site. Thus, the copy number increases with each transposition. *Retrotransposons* move via the synthesis of DNA copies of the RNA transcribed from the element (''retro'' for reverse flow of genetic information, RNA → DNA, rather than DNA → RNA as in transcription). Some of the retrotransposons are closely related to retroviruses, or RNA tumor viruses, that use this RNA → DNA lifestyle.

Transposable genetic elements are major components of genomes, making up more than 40% of the DNA in the human genome and perhaps as much as 80% of the maize genome. They are responsible for a large number of spontaneously occurring mutations and play important roles in genome evolution. Crossing-over between two copies of a transposon in a chromosome will produce deletions or inversions depending on their orientations with respect to each other. Two transposons can also move the segment of DNA between them from one location to another if they transpose simultaneously. Indeed, transposable elements are in part responsible for the rapid spread of antibiotic and drug resistance in bacteria, a phenomenon of major concern to the medical community.

5.5 Physical Maps of Chromosomes

Whereas genetic maps are based on recombination frequencies, *physical maps* of chromosomes are based on the molecular distances – base pairs (bp), kilobases (kb, 1000 bp), and megabases (Mb, 1-million bp) – separating genes or molecular markers. Physical distances do not correlate directly with genetic map distances because recombination frequencies are not always proportional to molecular distances. However, the two are often reasonably well correlated in euchromatic regions of chromosomes. In humans, 1 cM is equivalent, on average, to about 1 Mb of DNA.

When mutations change the nucleotide sequences in restriction enzyme cleavage sites, the enzymes no longer recognize them. Other mutations may create new restriction sites. These mutations result in variations in the lengths of the DNA fragments produced by digestion with various restriction enzymes. Such *restriction fragment length polymorphisms*, or *RFLPs*, have proven invaluable in constructing detailed genetic and physical maps of chromosomes. The RFLPs can be mapped just like other genetic markers; they segregate in crosses as though they are codominant alleles. Correlations between genetic and physical maps can be established by positioning clones of genetically mapped genes or RFLPs on the physical map. Markers that are mapped both genetically and physically are called *anchor markers*. They anchor the physical map to the genetic map and vice versa. *Sequence-tagged sites* (*STSs*) – unique genomic DNA sequences 200 to 500 base pairs long – and *expressed-sequence tags* (*ESTs*) – DNA copies of mRNAs – are often used as hybridization probes to anchor physical maps to genetic maps.

In humans, the most useful RFLPs involve short sequences that are present as tandem repeats. The number of copies of each sequence present at a given site on a chromosome is highly variable. These sites, called *variable number*

tandem repeats (*VNTRs*) are highly polymorphic. VNTRs vary in fragment length because of differences in the number of copies of the repeated sequence between the restriction sites. *Microsatellites* are another class of polymorphisms that have proven extremely valuable in constructing high-density maps of eukaryotic chromosomes. Microsatellites are polymorphic tandem repeats of sequences only two to five nucleotide pairs long. They are called microsatellites because they are a subset of the satellite sequences present in the highly repetitive DNA of eukaryotes. When two or more segments of a chromosome have been identified, mapped physically, and shown to overlap, they are said to form a *contig*, and their combined physical maps form a *contig map*.

5.6 Map-position-based Identification of Genes

The availability of detailed genetic and physical maps of chromosomes permits researchers to isolate genes on the basis of their location in the genome. This approach, called *positional cloning*, can be used to identify any gene regardless of its function. The steps in positional cloning are illustrated in Fig. 22. The gene is first mapped to a specific region of a chromosome by genetic crosses or, in the case of humans, by pedigree analysis. The gene is next localized on the physical map of this region of the chromosome.

Positional cloning involves ''walking'' or ''jumping'' along a chromosome until the desired gene is reached. Chromosome walks are initiated by the selection of a molecular marker (e.g. RFLP or gene clone) close to the gene and the use of this clone as a hybridization probe to screen a genomic library for overlapping sequences. Physical maps are constructed for the overlapping clones identified in the library screen, and the restriction fragment farthest from the original probe is used to screen a second genomic library constructed by using a different restriction enzyme or prepared from a partial digest of genomic DNA. Repeating this procedure several times and isolating a series of overlapping genomic clones allow a scientist to walk the required distance along a chromosome to the desired gene.

When the distance from the closest molecular marker to the gene of interest is large, a technique called chromosome jumping can be used to speed up an otherwise laborious walk. Each jump can cover a distance of 100 kb or more. Like a walk, a jump is initiated by using a molecular probe such as an RFLP as a starting point. However, with chromosome jumps, large DNA fragments are prepared by partial digestion of genomic DNA with a restriction endonuclease. The large genomic fragments are then circularized with DNA ligase. A second restriction endonuclease is used to excise the junction fragment from the circular molecule. This junction fragment will contain both ends of the long fragment; it can be identified by hybridizing DNA fragments separated by gel electrophoresis to the initial molecular probe. A restriction map of the junction fragment is prepared, and a restriction fragment that corresponds to the distal end of the long genomic fragment is cloned and used to initiate a chromosome walk or a second chromosome jump. Chromosome jumping has proven especially useful in work with large genomes such as the human genome.

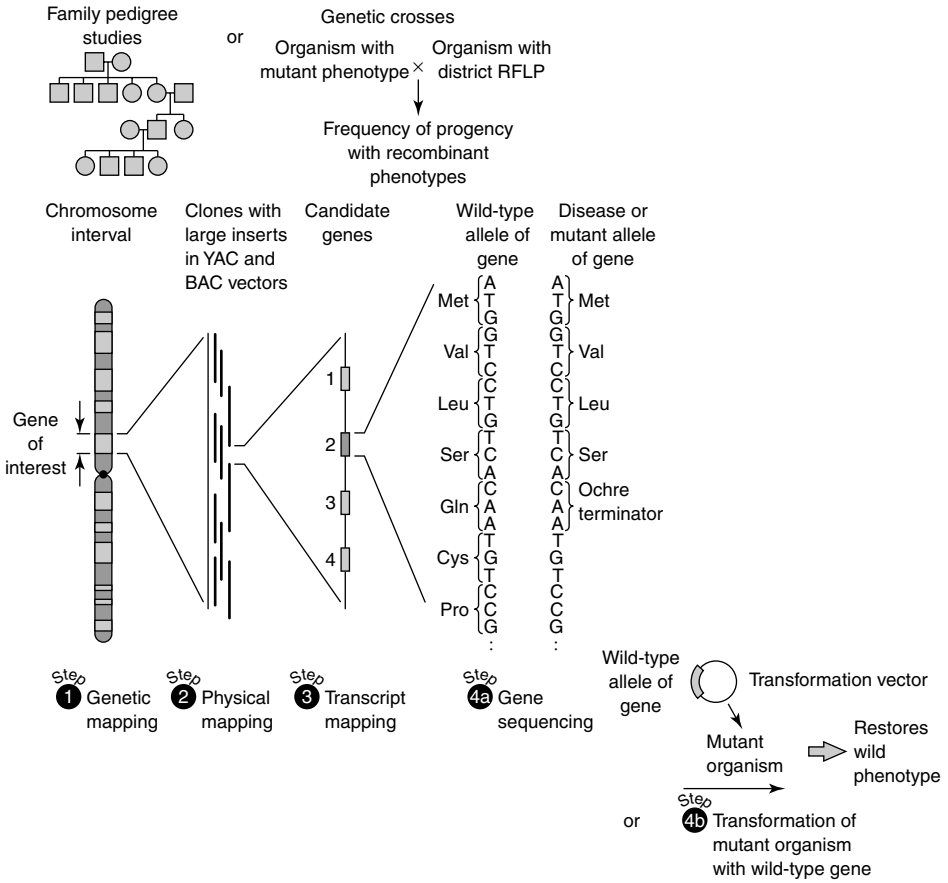

Fig. 22 Steps involved in cloning of genes on the basis of their location in the genome (positional cloning). The gene is first mapped to as small a region of a chromosome as possible. In humans, mapping must be done using family pedigree data, and candidate genes must be screened by comparing the sequences of genes from ''normal'' individuals with the sequences from individuals with the trait or genetic disorder. In other species, mapping is done using data from genetic crosses, and candidate genes are screened by transforming mutant organisms with the wild-type allele of the gene and seeing whether it restores the wild-type phenotype. (Reproduced from Snustad, D.P., Simmons, M.J., *Principles of Genetics*, 3rd edition, Copyright © 2003 by John Wiley & Sons, Inc., Hoboken, NJ, USA. This material is used by permission of John Wiley & Sons, Inc.)

Verification that a clone of the desired gene has been isolated is accomplished in various ways. In organisms such as *Drosophila,* verification is achieved by introducing the wild-type allele of the gene into a mutant organism and showing that it restores the wild-type phenotype. In humans, verification commonly involves determining the nucleotide sequences of the wild-type gene and several mutant alleles and showing that the coding sequences of the mutant genes are defective and unable to produce functional gene products.

Genome Scanning
High-speed survey of the presence or absence of landmarks throughout a genome and the measurement of their copy number in each locus.

Restriction Landmark
Use of restriction enzyme sites as guideposts throughout the genome.

Blocking (in RLGS)
Reduction of background by interfering with the incorporation of labeling reagents into nonspecific-damaged sites of DNA with pretreatment using enzyme reaction(s).

The restriction landmark genomic scanning (RLGS) technology is a method for high-speed survey of the presence or absence of restriction landmarks throughout a genome and the measurement of their copy number based on the new concept that restriction enzyme sites are used as landmarks. RLGS employs (1) direct end-labeling of the genomic DNA digested with a restriction enzyme and (2) high-resolution, two-dimensional electrophoresis. RLGS has the following advantages. (1) High speed–scanning ability. Thousands of restriction landmarks can be scanned simultaneously. (2) Scanning field can be extended by the use of different kinds of landmarks in an additional series of electrophoresis; (3) This method can be applied to any organism because direct labeling of restriction enzyme sites, and not the hybridization procedure, is employed as a detection system. (4) Spot intensity reflects the copy number of the restriction landmark. Thus, haploid and diploid genomic DNAs can be distinguished. (5) Using a methylation-sensitive enzyme, the methylated state of genomic DNA can be screened. Thus, RLGS is a very useful system not only for genome mapping but also for various studies in biological and medical fields, such as research for cancer development, aging, and so on.

1 Concept of "Genome Scanning"

Genome scanning is defined as high-speed survey of the presence or absence of landmarks throughout a genome and measurement of their copy number in each locus. Originally, the concept of "genome scanning" arose from the idea of overall detection of the physical condition of the whole genomic DNA. From this standpoint, it would be simplest to detect all fragments of genomic DNA generated by restriction enzyme cleavage after electrophoresis followed by ethidium bromide staining. Initially, efforts were made to visualize whole genomic DNA fragments according to this approach using the *Escherichia coli* genome. However, this approach was limited to small-sized genomes. As the complexity of the genome increases, the copy number of DNA molecules of the haploid genome equivalent decreases in the specific amount of genomic DNA and it becomes more difficult to separate and detect the DNA fragments. In the case of the human genome, which is 3×10^9 bp, a single copy locus per haploid genome of 1 μg human genomic DNA produces only 0.5 attomoles (5×10^{-19} mol) fragments.

To overcome this problem, scanning only landmark information was tried, ignoring the other genomic DNA regions. A landmark would be a guidepost on the genome, which can be visualized as signals through the assay method (scanning method), representing a one-to-one correspondence of a signal to its locus. The ideal landmark and scanning method should offer the following: (1) robust landmark signals that can be detected reproducibly, (2) high speed–scanning ability (multiplex scanning), (3) measurement of landmark copy number from its signal strength, (4) simple procedure and robotization, (5) expandability of scanning field, (6) applicability to any organism, (7) exportability of the information of landmark to any organism, and (8) exportability of the technique and the information to other laboratories.

As the most classic method, Southern hybridization initially provided a quantitative and qualitative method for visualizing landmarks directly from genomic DNA using a probe with a unique sequence. In this system, a signal specific to each locus can be detected because characteristic molecule recognition of DNA hybridization occurs in a sequence-specific manner. Next, a polymerase chain reaction (PCR) was developed as an alternative method for detecting landmarks. PCR is a technique for amplifying a region of several hundred base pairs, flanked by a pair of oligonucleotide primers. In the PCR technique, the specificity of signals depends on the specificity of hybridization of the primers to a unique genomic locus.

To facilitate the screening of genome DNA, two approaches can be considered for identifying landmarks on complex genomes such as mammals. One approach is the simplification of the procedure for detecting loci by establishing robotized systems. In Southern hybridization, using a unique probe and in PCR, for amplifying a unique sequence, a robust but a single landmark can be identified. To establish hybridization- or PCR-based genome scanning, the development of a robotized system is essential, because only one locus can be assayed in one procedure. The other approach is the development of a multiplex method by which multiple loci can be screened in one procedure. Typical techniques of hybridization-based and PCR-based multiplex methods are DNA fingerprinting using repeating sequences

(VNTR, IAP etc.) as probes and the Alu-PCR method respectively. Trials to identify mutant loci and construct genome mapping have proved successful in some cases using these conventional approaches based on the concept of genome scanning. However, the type of available repeating sequences limits the scanning field and scanning speed, because the basic principle of both approaches to produce signal specificity is sequence-to-sequence hybridization.

Our group has introduced a new concept termed *restriction landmark*, in which each restriction enzyme recognition site can be used as a landmark. On the basis of this concept, we developed a restriction landmark genomic scanning (RLGS) method, which employs (1) direct end-labeling of the genomic DNA digested with a restriction enzyme and (2) high-resolution, two-dimensional electrophoresis. This method provides an alternative multiplex approach to genome analysis. Because of the strict specificity of sequence recognition of the restriction enzyme, this technique enables us to scan multiple and robust landmarks. Here, we present the concept and method of RLGS, which allows restriction landmarks to be surveyed throughout a genome.

In 2003, the completion of human genome sequence was announced. The draft genome sequences of many other model organisms have also been reported. The database provides us with a substantial amount of information that can influence medicine, drug design, and industrial and agricultural production. The genome sequence is just a part of genetic information, however, because DNA modification, mainly methylation, is essential genetic and epigenetic information.

2 Principle of RLGS

2.1 Breakthroughs Enabling the Development of RLGS

Direct end-labeling followed by electrophoretic separation had been very difficult with genomic DNA of high complexity, such as those of mammals. However, three significant breakthroughs paved the way for the development of RLGS. First was the discovery of effective enzymes. Conventionally used 6-bp cutters produce too many DNA fragments that cannot be separated as discrete signals. Various 8-bp cutters or rare cutters were discovered, which could produce an appropriate number of DNA fragments for analysis. Second was the establishment of a high-resolution electrophoretic system. Methods of fine disk agarose gel electrophoreses for the first dimension (1st-D) have been developed to enable high-resolution electrophoretic separation. This enabled us to subject the 1st-D agarose samples to high-resolution polyacrylamide gel electrophoresis in the second dimension (2nd-D), because the thickness of the second polyacrylamide gel depends on the thickness of the first agarose gel. Third was the development of the technique for blocking nonspecific radioactive incorporation. As the genome size increases, the copy number of DNA fragments generated from the specific amount of DNA decreases. However, the background radioactivity produced by the incorporation into nonspecific-damaged sites of genomic DNA does not change. Therefore, the signal/noise ratio decreases, depending on the genome size. Generally, when the genome size increases to more than 1×10^8 bp, it becomes very difficult to

detect the signals, because they become buried in the background. To overcome this problem, we developed a blocking technique to reduce the nonspecific incorporation of radioactivity. The principle of the blocking technique is based on the incorporation of the dideoxynucleotide analog into the damaged sites, such as nicks, gaps, and/or double-strand breaks. After the blocking reaction, the radioactive nucleotides cannot be elongated by the polymerase reaction from the sites in which these nucleotide analogs are incorporated. Moreover, if a sulfur atom of the analog is connected to the phosphorus atom at a position in place of an oxygen atom in the molecules, such as dideoxy-[α-thio] nucleotide analogs, it is very difficult to eliminate it by the 3′ exonuclease activity of polymerase in the labeling step (Fig. 1).

2.2 The Principle and Procedure of RLGS

RLGS is a technique for scanning restriction landmarks at intervals of less than 1 Mbp. As mentioned above, the random cleavage caused during the preparation of sample DNAs affects the RLGS pattern. To produce a clear pattern with low background, DNA of high quality is essential. The critical factors are not only the average length and the extent of damage (nicks and gaps) to it but also the content of the DNA population, which is less than 10 kbp in length, because such small DNA fragments increase the background. In the DNA preparation procedure, more care should be taken to avoid enzymatic degradation (with endonuclease leaking from the lysosome and other enzymes in the lysis step), rather than mechanical shearing. Therefore, when DNA is prepared by proteinase K and the phenol extraction method, the samples should be treated for less than 10 min, with an excess of Proteinase K.

Figure 2 shows the entire procedure of the RLGS method. In comparison with conventional DNA electrophoresis, this procedure that consists of eight steps is specially designed to reduce the background generated by the incorporation of radioactivity in the blocking step (a) and to separate a large number of DNA fragments very precisely (high-resolution, two-dimensional electrophoresis, (b–f)).

(a) *Blocking*: The principle of the blocking procedure is mentioned above. This step is done to reduce the background generated by the incorporation of radioactivity into the nonspecifically damaged sites.

(b) *Landmark cleavage (with restriction enzyme A)*: This step is for cleavage of genomic DNA at the restriction landmarks. The type of restriction enzymes used should be chosen by the frequency of sites in the genome and the sensitivity of DNA methylation. The restriction enzyme B should be selected on the basis of the frequency of the restriction sites that have an appropriate number of spots that appear on the RLGS pattern.

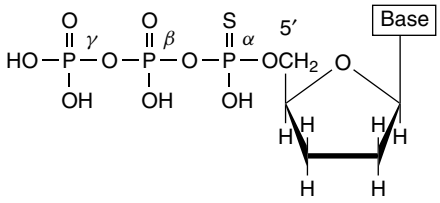

Fig. 1 Dideoxynucleotide analog for blocking method (dideoxynucleoside [α-thio] triphosphate).

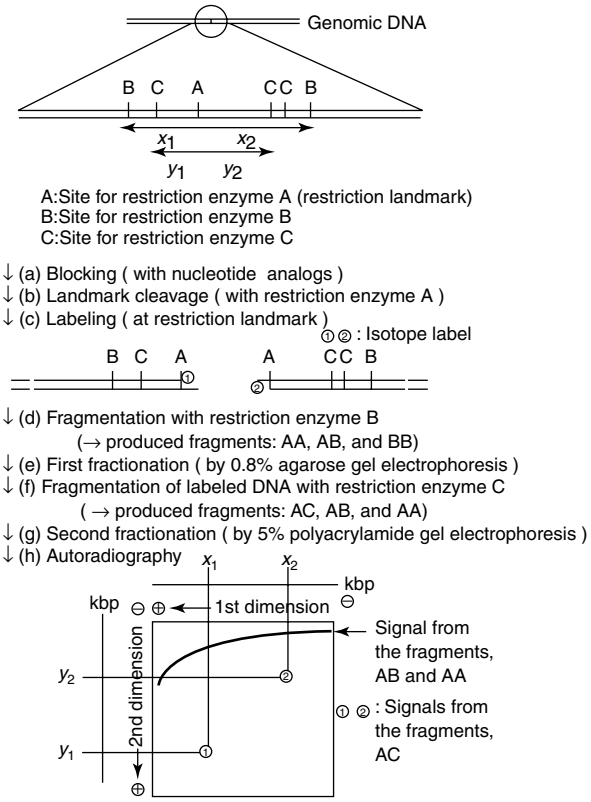

Fig. 2 Procedure for genome scanning by two-dimensional gel electrophoresis. x_1 and x_2 represent the distance from a restriction landmark to the neighboring site for restriction enzyme A or B. y_1 or y_2 represent the distance from the site of A to C. 1 and 2 indicate the labeled sites at the end of the landmark.

The number of analyzable spots is limited to less than 3000 spots in one gel by the resolution of the present technique. DNA methylation affects the RLGS pattern when methylation-sensitive enzyme is used as restriction enzyme A. In other words, the change of DNA methylation throughout the genome can be scanned, using a methylation-sensitive enzyme. Further discussion is presented below (see Sect. 5).

(c) *Labeling*: The labeling method depends on the shape of the end of the restriction fragment. In the case of the 5′-protruding end, a filling reaction of [α-^{32}P] deoxynucleotide with DNA polymerase is used. And for labeling at the 3′-protruding ends (or blunt end), a reaction of addition of [α-^{32}P] dideoxynucleotide with terminal deoxynucleotidyl transferase (terminal transferase) at the 3′ end of the DNA fragments is used (Hayashizaki, Y. et al. (1995) VCH Publishers, pp. 813–817).

(d) *Fragmentation of labeled DNA with restriction enzyme B*: This step is for further cleavage of the labeled genomic

DNA at the restriction landmark sites in a test tube. Because the total length of human or other mammalian genomic DNA is approximately 3×10^9 bp, more than 3000 DNA fragments with an average length of 1 Mbp will be produced by digestion with a restriction enzyme, even if *Not*I, the most infrequent 8-bp recognition enzyme, is used. However, such long DNA fragments cannot be prepared from DNA resources, such as cancer tissues, and, even if these DNA fragments were to be separated, pulse-field gel electrophoresis is used although its resolution is not enough to analyze so many DNA fragments. To solve this problem, we employed the digestion reaction of labeled fragments with restriction enzyme B, which appears more frequently in the genome than restriction landmarks. Owing to reduction in the length of the DNA fragments, the high-resolution disc agarose gel can be used, in which the entire resolution range is expanded to more than 40 cm.

In the case in which restriction enzyme A is used and the number of restriction sites are more than approximately 6000 in the genome (average length of this enzyme is less than 500 kbp), the treatment of restriction enzyme B is sometimes skipped. At the present level of the technique, too many such spots cannot be separated in one gel. However, if the fragmentation with restriction enzyme B is omitted, the average length of DNA fragments of almost all 8-bp cutters and rare cutters will be more than 30 kbp and these fragments will be trapped at the top of the agarose gel, resulting in reduction of the spot number. The final RLGS profile is the screening of an appropriate number of spots dispersed over most of a two-dimensional field.

(e) *First fractionation by agarose gel electrophoresis*: To obtain a good RLGS profile in the 1st-D agarose gel electrophoresis, the gel should be as thin and fine as possible, and the samples should be electrophoresed as long as possible to precisely separate more than 3000 signals. The prototype procedure using a horizontal gel of this step is described in other literature.

(f) *Fragmentation of labeled DNA with restriction enzyme C*: To resolve so many signals, these fragments should be subjected to further separation. The agarose disc gel should be treated with reaction mixture of restriction enzyme C. Usually, an enzyme whose restriction sites are more frequent than those of restriction enzyme B, such as a 4-bp cutter, should be used as the restriction enzyme C. Owing to this cleavage reaction, the DNA fragments can be electrophoresed depending on the distance from the site of restriction enzyme A to C (γ_1 and γ_2 in Fig. 2).

(g) *Second fractionation*: After the connection of the 1st-D agarose gel to the 2nd-D polyacrylamide gel, the DNA fragments are subjected to further 2nd-D gel electrophoresis. The sizes of the DNA fragments range from 2 kbp to 70 bp. Though technically vertical gels are used, original protocol has been described as the horizontal electrophoresis system.

(h) *Autoradiography*: The final gel samples are dried and autoradiographed.

3 Techniques

In this section, we describe the most recent protocol, which uses a vertical electrophoresis system. Use of an alternative

horizontal electrophoresis system has been described in other literature.

3.1 Preparation of Genomic DNA

3.1.1 Materials and Stock Buffers

Materials Proteinase K (Nakalai), RNase A (Nakalai), phenol (the commercially available phenol should be distilled), chloroform, isoamyl alcohol, sodium sarkosylate, 8-hydroxyquinoline, 50-mL Falcon tube, mortar and pestle, and dialysis tube.

Stock buffers

- TE: 10 mM Tris-Cl pH 7.5, 1 mM EDTA.
- PCI (phenol-chloroform-isoamyl-0.1% 8-hydroxyquinoline): Distilled phenol, chloroform, and isoamyl alcohol are mixed in a ratio of 50 : 49 : 1, and 8-hydroxyquinoline is adjusted to 0.1% in the final mixed reagent. PCI should be buffered with TE.
- Lysis buffer: 1 mg mL^{-1} Proteinase K, 150 mM EDTA, 1% sarkosyl, and 10 mM Tris-Cl pH 8.0.

3.1.2 DNA Preparation

A sample of 0.5 g of tissue wrapped in aluminum foil is frozen with liquid nitrogen. The sample is crushed with a hammer, and then powdered in a mortar that has been chilled in liquid nitrogen. For the study of cell lines, a cell pellet washed with phosphate-buffered saline (PBS) can be used in place of the powdered tissue. The sample is transferred into a 50-mL Falcon tube, followed by the addition of 20 mL lysis buffer. Stirring with a spatula gives a viscous sample. The mixture is incubated at 55 °C for 5 min and then 20 mL of PCI is added immediately, followed by gentle stirring until the border between the aqueous and phenol phases disappears. The sample is centrifuged at 3000 rpm for 30 min with RL101 swing rotor (Tomy). The aqueous phase is transferred into a new 50-mL Falcon tube. This phenol extraction should be repeated more than twice. The sample is dialyzed overnight against TE that has been autoclaved. After recovery from dialysis tube, 20 µL of 1 mg mL^{-1} boiled RNase A is added to digest RNA and is incubated for 2 h at 37 °C. The elimination of RNA is confirmed by 0.8% agarose electrophoresis using 1 µL of the reaction mixture. Next, PCI extraction is performed to inactivate RNase A. Ethanol, 40 mL, is added with gentle stirring. The precipitate is transferred to an Eppendorf sample tube and suspended in 500 µL of TE.

3.2 Blocking and Direct DNA Labeling at Restriction Landmark

3.2.1 Materials and Stock Buffers

Materials DNA polymerase I (Toyobo), deoxynucleoside [α-thio] triphosphates (dGTP[α]S, dATP[α]S, dCTP[α]S, dTTP[α]S, (Toyobo)), dideoxynucleoside [α-thio] triphosphates (ddGTP[α]S, ddATP[α]S, ddCTP[α]S, ddTTP[α]S, (Toyobo)), dideoxynucleoside triphosphates (ddGTP, ddATP, ddCTP, ddTTP, (Toyobo)), [α-^{32}P] dGTP (3000 Ci $mmol^{-1}$) (Amersham, UK), [α-^{32}P] dCTP (6000 Ci $mmol^{-1}$) (Amersham), *Not*I (Takara), *Eco*RV (Toyobo), *Mbo*I (Takara), Sequenase Ver. 2.0 (Amersham), terminal deoxynucleotidyl transferase (Takara), bromophenol blue (BPB), xylene cyanol (XC), and dithiothreitol (DTT).

Stock buffers

- 10 × high buffer (HB): 500 mM Tris-Cl (pH 7.4), 100 mM MgCl2, 1 M NaCl, and 100 mM DTT.

- 10 × medium buffer (MB): 500 mM Tris-Cl (pH 7.4), 100 mM MgCl2, 500 mM NaCl, and 100 mM DTT.
- 4 × blocking buffer (BB): 4 × MB, 1.6 μM dGTP[αS], 0.8 μM dCTP[αS], 16.0 μM ddTTP[αS] (or ddTTP), and 16.0 μM ddATP[αS] (or ddATP).
- TE buffer: 10 mM Tris-HCl (pH 7.4), 1 mM EDTA.
- PCI; refer to Sect. 3.1.1.

3.2.2 Procedures of Blocking, Restriction Enzyme Digestions, and Labeling

Blocking The genomic DNA is treated with 1.75 units of DNA polymerase I in 10 μL of 1 × high buffer in the presence of 0.4 μM dGTP[αS], 0.2 μM dCTP[αS], 4.0 μM ddTTP[αS] (or ddTTP), and 4.0 μM ddATP[αS] (or ddATP). ddTTP[αS] and ddATP[αS] (Fig. 1) rather than ddTTP and ddATP are recommended to obtain a good pattern. This combination of nucleotide analog is applied to the labeling of *Not*I landmarks. In this blocking reaction, the deoxynucleoside [α-thio] triphosphate(s) (dXTP[αS]), which is incorporated into the site of landmark cleavage (dGTP[αS] and dCTP[αS] in this case), should be chosen as 0.4 μM or 0.2 μM of dXTP[αS] (the concentration depends on the specific activity of the radioactive compound used in the labeling step) and the dideoxynucleoside [α-thio] triphosphate(s) (ddYTP[αS]), which cannot be incorporated into the site of landmark cleavage (ddTTP[αS] and ddATP[αS]), should be chosen as 4.0 μM of ddYTP[αS]. This reaction mixture is incubated at 37 °C for 30 min. DNA polymerase I is inactivated by heating at 65 °C for 30 min.

Protocol 1

7.0 μL	sample DNA
2.5 μL	4 × blocking buffer
0.5 μL	DNA polymerase I [3.5U/L]
10 μL	total

↓ Mix with pipetting
↓ Incubate at 37 °C for 30 min
↓ Incubate at 65 °C for 30 min.

Landmark cleavage DNA is digested with enough units of landmark restriction enzyme A, such as *Not*I. The reaction mixture is incubated at 37 °C for 2 h.

Protocol 2

10.0 μL	sample DNA
2.0 μL	10 × HB
2.0 μL	10 × HB
2.0 μL	*Not*I [10 U μL^{-1}]
6.0 μL	H_2O
20.0 μL	total

↓ Mix with pipetting
↓ Incubate at 37 °C for 2 h.

Labeling The cleavage ends are filled in with 1.3 units of Sequenase Ver. 2.0 in the presence of 0.165 μM [α-^{32}P] dGTP (3000 Ci $mmol^{-1}$) and 0.165 μM [α-^{32}P] dCTP (6000 Ci $mmol^{-1}$) at 37 °C for 30 min. The polymerase reaction is stopped by heating up to 65 °C for 30 min.

Protocol 3

20.0 μL	sample
0.3 μL	1M DTT
1.0 μL	[α-^{32}P]dGTP
1.0 μL	[α-^{32}P]dCTP
0.1 μL	Sequenase Ver. 2.0 [13 U μL^{-1}]
22.4 μL	total

↓ Mix with pipetting
↓ Incubate at 37 °C for 30 min
↓ Incubate at 65 °C for 30 min.

Cleavage with restriction enzyme B The second digestion is performed with restriction enzyme B, such as *Eco*RV, in 30 μL of 1 × high buffer. The final reaction mixture is as shown in Protocol 4. The reaction mixture is incubated at 37 °C for 1 h.

Protocol 4

22.4 μL	sample DNA
1.0 μL	10 × HB
2.0 μL	*Eco*RV [10 U μL^{-1}]
4.6 μL	H_2O
30.0 μL	total

↓ Mix with pipetting
↓ Incubate at 37 °C for 1 h.

3.3 Two-dimensional Separation with Electrophoresis

3.3.1 Materials, Apparatus, and Stock Solution

Materials

- SeaKem GTG agarose (FMC); acrylamide (Nakalai); methylenebisacrylamide (Nakalai); ammonium persulfate (Nakalai); bovine serum albumin (BSA) (Sigma, fraction V); disposable plastic syringes (1 mL, 5 mL); needles, three-way stopcocks for syringes.
- 10 × 1st-D buffer (for 1st-D): Dissolve 242 g Tris, 109 g sodium acetate trihydrate, 42 g NaCl, 23.4 g EDTANa2 in 1.8 L of H_2O and adjust the pH to 8.15 with acetic acid. Adjust the volume to 2 L and autoclave it. The pH of the 1 × buffer is 8.0.
- 10× tris-borate, EDTA (TBE) buffer (for 2nd-D): Dissolve 1210 g Tris, 770 g boric acid, and 75 g EDTANa2 in H_2O and adjust to 20 L. Final concentration for electrophoresis is 1 × TBE.
- 6 × dye solution: 0.25% BPB, 0.25% × C in (30% glycerol) in H_2O.
- 10% ammonium persulfate (Nakalai).
- N,N,N′,N′-Tetramethylethylenediamine (TEMED) (Nakalai)

Gel

- 1st-D agarose gel: 0.8% agarose (SeaKem GTG) in 1 × 1st-D buffer with 5% sucrose. (Adjust 0.24 g agarose to 30 mL with 1 × 1st-D buffer containing 5% sucrose.)
- Connecting gel: 0.8% agarose (SeaKem GTG) in 1 × TBE with 5% sucrose. (Adjust 0.24 g agarose to 30 mL with 1 × TBE containing 0.2 mL 6 × dye without glycerol.)(note) Polyacrylamide gel should be prepared just before the use for 2nd-D gel electrophoresis.

Electrophoretic apparatus

- 3.0 mm i.d., 3.6 mm o.d., 10 m (for *in situ* digestion) (#9), Teflon tubing, (Nichias).
- 3 mm i.d., 5 mm o.d., 1 m (No. 7078BR), Silicon tubing (for 1st-D), (Sanplatec).
- 1st-D gel holder (composed of 4 mm i.d. and 60-cm long glass tube with a 2.4 mm i.d. and 63-cm long Teflon tubing inside. Silicon stopper #4 with a hole is set at 4 cm below the top edge).
- Electrophoretic tank for 1st-D (Fig. 3).
- Electrophoretic tank for 2nd-D (Figs. 4 and 5).

Note: 1st-D gel holder and electrophoretic tanks for 1st-D and 2nd-D are manufactured and supplied by Biocraft Inc., Tokyo, Japan: URL, http://www.bio-craft.co.jp; E-mail, info@bio-craft.co.jp.

Preparation of the gel holder for the vertical 1st-D disc gel The prototype 1st-D disc gel method with Teflon tubing was originally developed by Asakawa. In this protocol, we

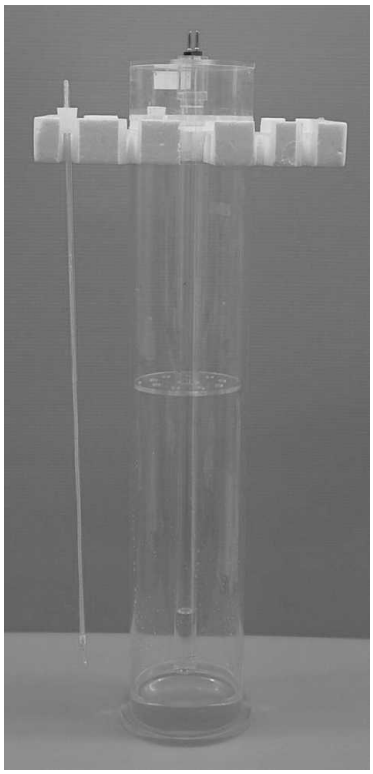

Fig. 3 1st-D electrophoretic tank with 1st-D gel holder on the hanging parts.

introduce an extensively modified Teflon tubing method that was adapted from Okazaki et al.

3.3.2 Gel Casting for Vertical 1st-D Disc Gel

- Melt the agarose gel solution in a microwave oven.
- Cool the solution down to 55–65 °C (Fig. 6).
- Connect a 5-mL plastic syringe fitted with a three-way stopcock to the top edge of the 1st-D gel holder with a 3-cm long silicon tubing.
- Suck up the gel solution (Fig. 6) gradually to reach the line (1 cm below the top).
- Close the stopcock and hold it on the support stand (Figs. 7 and 3).
- Wait for 15 min for the gel to solidify.
- Open the stopcock to the air and disconnect it.
- Add 350 mL of 1 × 1st-D buffer to the cathodal bottom tank.
- Fit each gel on the anodal top tank at the silicon stopper.
- Place the anodal tank on the cathodal tank and fill the anodal tank with 350 mL of 1st-D buffer.

3.3.3 Running 1st-D Gel

- Apply an aliquot of sample containing 1.5 μg DNA.
- Electrophoresis at 100 V for 1 h and 230 V for about 23 h until the BPB migrates 50 cm.

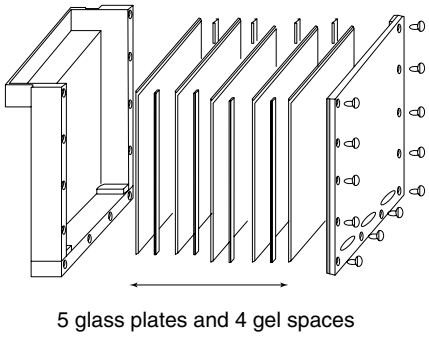

Fig. 4 Assembly of glass plates in the 2nd-D electrophoretic apparatus.

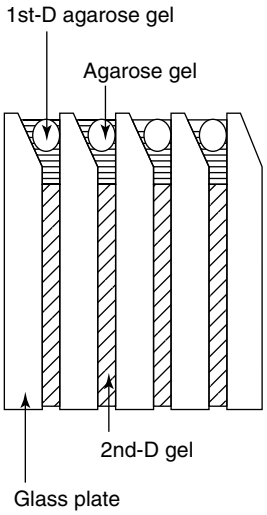

Fig. 5 Partial cross-section of a 2nd-D electrophoretic apparatus after the 1st-D gel connection.

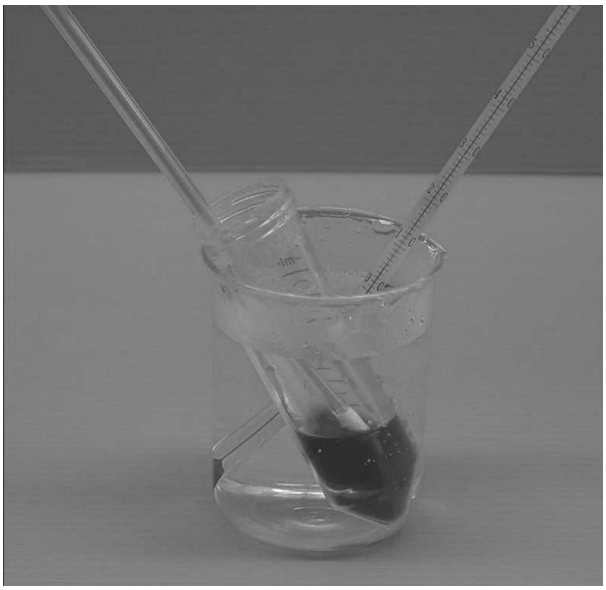

Fig. 6 Casting of 1st-D gel.

3.3.4 **Extruding the Gel**

- After electrophoresis, remove the cathodal top buffer with an aspirator and take out each gel holder.
- Expel the gel slowly using a cut-off yellow tip of a 1-mL syringe (Fig. 8).
- Cut off the gel 4 cm from the bottom edge (Fig. 9).
- Soak the gel in 50-mL Falcon tube containing 40 mL of 1 × HB (Fig. 10).
- Sway the tubes gently and equilibrate the buffer system of the gel for 10 min.

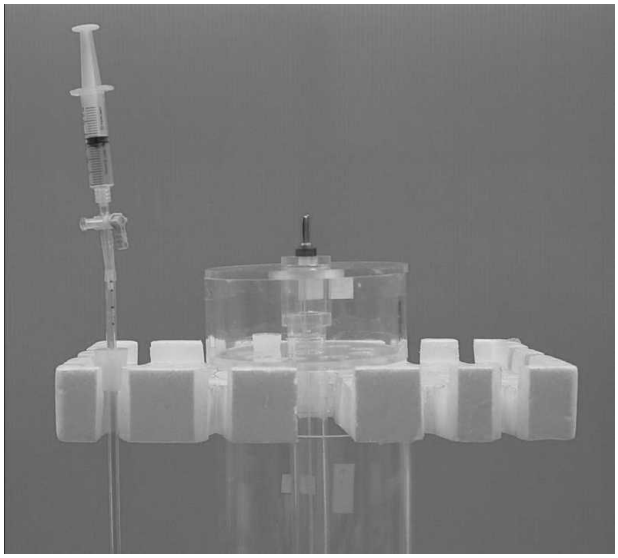

Fig. 7 Magnified view of the hanging parts and 1st-D gel holder.

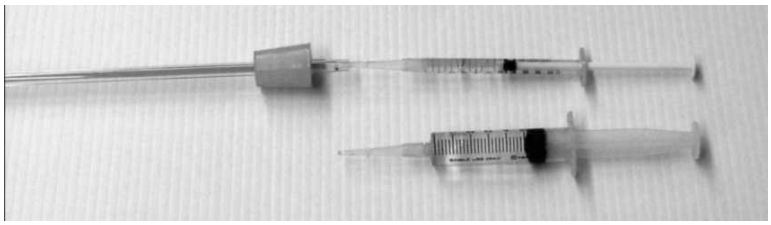

Fig. 8 Syringes to expel the 1st-D gel.

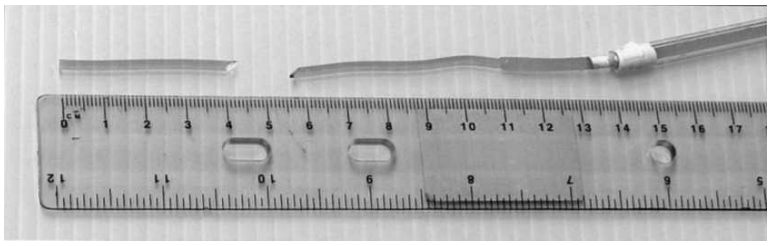

Fig. 9 Cutting the 1st-D gel.

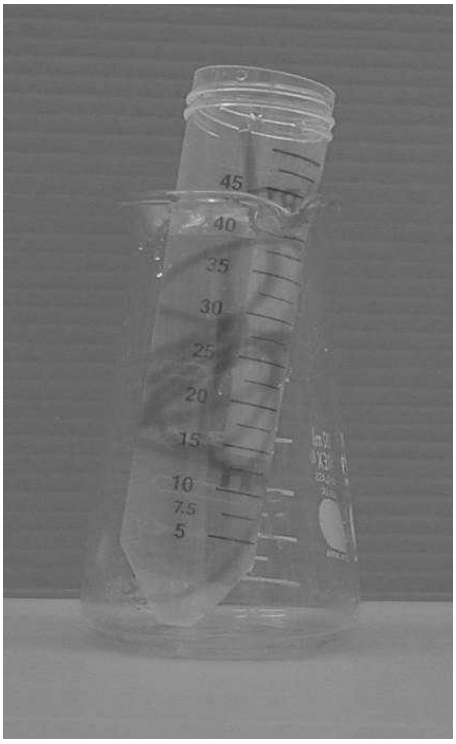

Fig. 10 Changing the buffer system for the 1st-D gel.

- Change the buffer again and equilibrate completely for 10 min.

3.3.5 *In Situ* Restriction Enzyme Digestion

Prepare Teflon tubing with an inside diameter that is slightly larger than that of the gel. Mount the 10-mL plastic syringe and connect it to the 3.0 mm i.d. and 45-cm long Teflon tubing (#9) with 3-cm silicon tubing.

- Pour the equilibrated gel into a tray containing 20 mL of 1 × HB (Fig. 11).
- Gently suck up the gel into the Teflon tubing (Fig. 11).
- Remove the buffer inside the Teflon tubing.
- Fill the tubing with 1.5 mL of enzyme solution, 1500 units of restriction enzyme (*Mbo*I), and 0.01% BSA by sucking up slowly (Fig. 12).
- Remove the syringe and make loop the tubing by connecting one end to the other.
- Put the looped tubing into a plastic bag (Fig. 13).
- Seal the bag and incubate at 37 °C for 2 h.

3.3.6 Preparation of 2nd-D Gel

Preparation of acrylamide of gel solution The polyacrylamide gel solution should be prepared just before the 2nd-D gel electrophoresis. Usually, 5% polyacrylamide gel is employed. Dissolve 145 g acrylamide, 5 g methylenebisacrylamide, 2-g ammonium persulfate in 3 L of 1× TBE buffer. Add 0.8 mL TEMED just before solidifying the gel.

2nd-D gel assembly Figures 4 and 5 show the recent type apparatus for the vertical 2nd-D electrophoretic system. This is composed of upper and lower electrophoretic tank and a box containing 5 glass plates with 1-mm thick spacers between the glass plates, which enables the preparation of 4 gels by pouring acrylamide solution into the box in one procedure. It is not necessary to reset the glass plates onto the electrophoretic apparatus. This apparatus can be also used as an electrophoretic tank itself.

The glass plates for 2nd-D are 480 (W) × 410 (H) × 5 (thick) mm in size. The gel is cast into a gel box carrying 4 gel spaces, which are made by 5 glass plates neatly placed side by side with 1-mm gel spacers in between. After the gel plates and spacers are assembled, acrylamide gel solution is poured. The gel surface is adjusted

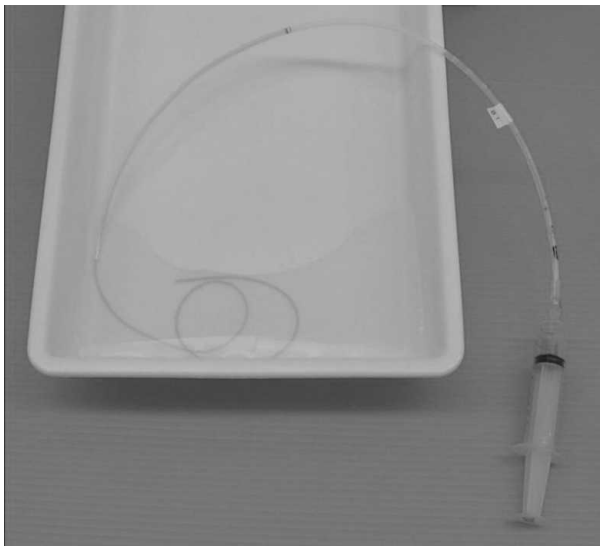

Fig. 11 Using a syringe to pull the 1st-D gel up into the Teflon tubing.

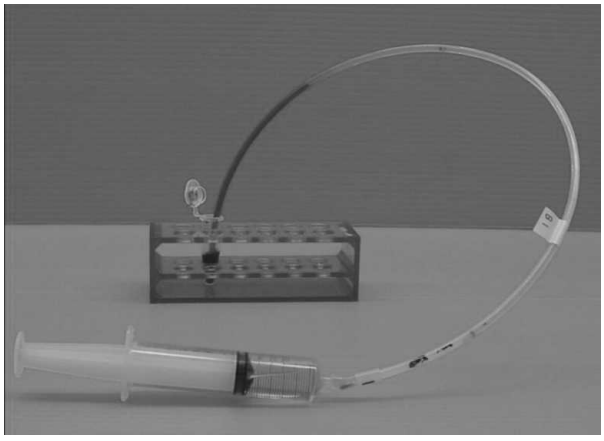

Fig. 12 Filling the tubing with enzyme C solution.

5 mm below the tapering edge of the glass plate. 1 mL of 2-butanol is laid gently on each acrylamide gel solution. Wait for 1 h for the gel to solidify.

3.3.7 Running 2nd-D Gel

- Rinse the top of the gel with 1 × TBE to remove 2-butanol and wipe the surface with a sheet of paper (Kimwipe) to remove the TBE completely.
- After 2 h, digestion with *Mbo*I expels the 1st-D gel from the tubing into a 50 mL-Falcon tube containing 40 mL of 1 × TBE.
- Shake the tubes gently and equilibrate the buffer system of the gel for 10 min.

Fig. 13 Tubing loop in the plastic bag.

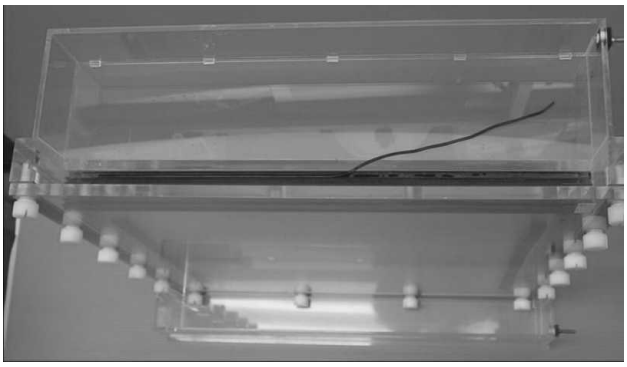

Fig. 14 Placing the 1st-D gel on the 2nd-D gel (top view).

- Discard the buffer and place the 1st-D gel on the top of 2nd-D acrylamide gel (Figs. 14 and 15).
- Connect 1st-D gel and 2nd-D gel with 2 mL of connecting gel using a 5-mL syringe with 22 g needle.
- Pour 0.2 mL of 6 × dye solution on the gel.
- Electrophorese at 100 V for 1 h and 150 V for about 23 h till the BPB reaches the bottom.

3.3.8 **Gel Drying and Autoradiography**

- Dry up the gel at 80 °C.
- Autoradiography using XAR5 (Kodak) in the cassette with intensified screen, Quanta Rapid™ (Sterling, see supplier, Knight Imaging Products at URL, http://www.ssl.gb.com/knight/intensifying_screens.htm).
- 24 h for short exposure.
- 7 to 10 days for long exposure (Fig. 16).

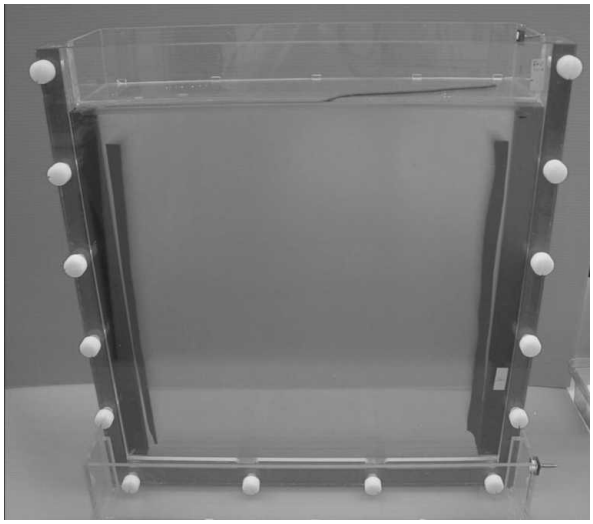

Fig. 15 Placing the 1st-D gel on the 2nd-D gel (side view).

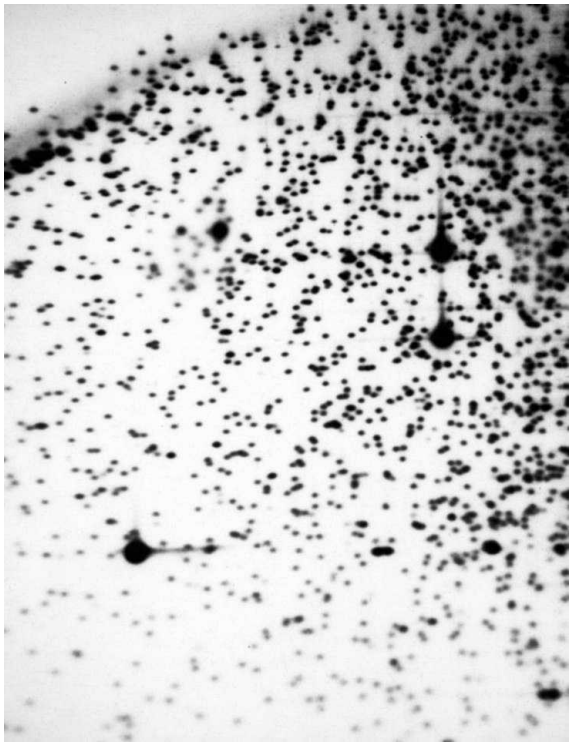

Fig. 16 RLGS profile of hamster genome DNA. *Not*I, *Eco*RV, and *Mbo*I were used as restriction enzymes A, B, and C respectively.

4 RLGS Pattern and Its Advantages

Figure 16 shows the resulting RLGS profile using *Not*I, *Eco*RV, and *Mbo*I as restriction enzyme A (restriction landmark), B, and C respectively. As shown in Fig. 2, the x, y coordinates $((x_1, y_1), (x_2, y_2))$ of each spot indicate the distances from the site of restriction enzyme A through B, and from A through C, respectively. In spite of the large size of mammalian or plant genomes, it is inconceivable that two sets of identical valued parameters (x, y) were to be produced from different landmarks on the genome. Therefore, one spot on the RLGS profile corresponds to one locus. In the mice RLGS profile, more than 2500 spots appeared in one gel, indicating that the information corresponds to more than 2500 times that from Southern hybridization or PCR with unique probes (primers). The high resolution of this system results from the two-dimensional system of combining agarose gel and polyacrylamide gel, and almost all the regions of the two-dimensional area are used efficiently to separate a large amount of spots.

RLGS has the following advantages for genome scanning. (1) It has high speed–scanning ability. Thousands of restriction landmarks can be scanned simultaneously. (2) The scanning field can be extended by using different kinds of landmarks in an additional electrophoresis series. More than 10 kinds of restriction enzymes can be used (Table 1). (3) This method can be applied to any organism because direct labeling of restriction enzyme sites, and not hybridization procedure, is employed as a detection system. (4) Spot intensity reflects the copy number of the restriction landmark. In Fig. 16, several enhanced spots can be seen. These spots are derived from ribosomal DNA, which is the typical repetitive sequence in mammalian genome. The fact that haploid and diploid genomic DNAs can be distinguished in RLGS will be used for linkage analysis. (5) Using methylation-sensitive enzyme, the methylated state of genomic DNA can be screened (see Sect. 5). (6) When CpG-rich enzymes, such as *Not*I, *Bss*HII and so on are used, CpG islands near the genes are preferentially screened. In the case of *Not*I, 89% of all *Not*I spots are located on or near the transcripts. Thus, RLGS is very advantageous compared with hybridization-based and PCR-based genome scanning methods.

Tab. 1 Landmark enzymes A (both vertebrate methylation-sensitive and -insensitive), B and C.

Enzyme C
*Mbo*I, *Hin*fI

5 Screening for DNA Methylation Using RLGS-M

The RLGS method can be used in two ways. One is for genome scanning of the copy number of each locus corresponding to a spot using a methylation-insensitive enzyme as a restriction landmark. The other is for the detection of DNA methylation throughout the genome using a methylation-sensitive enzyme. Table 1

lists both types of restriction enzymes. Generally, the only known site for DNA methylation is the 5-position of the cytosine residue (5MeC), which is preferentially located on the palindromic dinucleotide 5′CG3′/5′GC3′. The 5MeCpG methylation-insensitive enzyme cleavage is not affected by DNA methylation in the vertebrate genome. The recognition sites of *Pac*I and *Swa*I do not include the C residue, and the site for Sse8387I also does not include the CG sequence, although the population of 5MeC located on CG sequence is not small. Therefore, when using these enzymes on the RLGS profile, the intensity of the spots depends entirely on the copy number of the corresponding locus.

As shown in Fig. 17 (RLGS-M, restriction landmark genomic scanning for DNA methylation), the intensity of the RLGS spots changes depending on DNA methylation when a 5MeCpG-sensitive enzyme is used as restriction enzyme A. If both alleles of the restriction landmark for a methylation-sensitive restriction enzyme, such as *Not*I, *Bss*HII and so on are demethylated, the corresponding spot displays full intensity. However, if one or both of the alleles are methylated, the spot intensity is reduced by half or disappears (Fig. 17). Thus, the degree of methylation can be screened by taking advantage of methylation-sensitive enzymes. Examples of this have been reported in other literature.

The RLGS method described here can be applied to many biological fields such as, cancer research (detection of amplification, loss of heterozygosity, methylation change), high-speed genome mapping (a large number of analyzable loci), isolation of imprinting genes, identification of individuals, and phylogenic analysis of species. Thus, the RLGS method is very useful for scanning not only the change of copy number of each locus but also the change in DNA methylation.

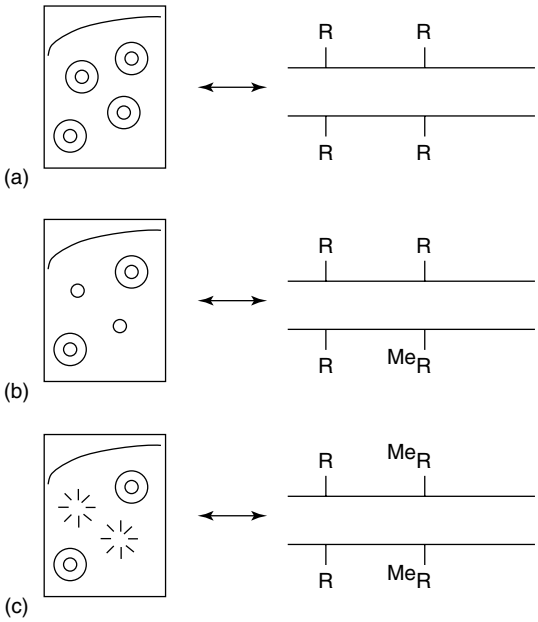

Fig. 17 Schematic representation of alteration in spot intensity due to genomic DNA methylation. (a) when both alleles are demethylated, the spots show diploid intensity; (b) when one allele is methylated, the corresponding spot shows half intensity; (c) when both alleles are methylated, the spots disappear. R, restriction landmark; MeR, the methylated restriction site.

6 Virtual RLGS

To develop analyses using RLGS profiles, the most important step is the identification of polymorphic spots. However, the amount of DNA available for cloning in a single spot is very small. In addition, the isolated-out acrylamide gel fragment contains two thousand times as many nonlabeled DNA fragments as the labeled DNA fragments. Therefore, it sometimes has the difficulty to clone the target DNA fragment. To overcome this problem for organisms where the entire genomic DNA sequence is known, we have developed a novel and efficient computer simulation to identify the spots, which we call RLGS pattern-designated virtual imaging restriction landmark genome scanning (Vi-RLGS). We used the *Arabidopsis* genome sequence to construct a Vi-RLGS system because its entire nuclear genomic DNA sequence has recently been reported, although there are a few small gaps.

First, a computer simulation for the RLGS procedure was written, following the flowchart shown in Fig. 2. In this simulation program, the landmark restriction enzymes and the recognition sites are indicated by A. Similarly, B and C indicate the second and third restriction enzymes, respectively. Therefore, ''AA,'' ''AB,'' ''AC,'' ''BB,'' ''BC,'' and ''CC'' indicate DNA fragments with the respective sites at either end. In step (b), the DNA is digested with enzyme A. Next, it is digested with enzyme B, and ''AA'' and ''AB'' fragments are used in the following step. In step (f), in-gel digestion with enzyme C following 1st-D electrophoresis is performed, and step (g) involves 2D-electrophoresis in the computer simulation. Presently, there are some gaps in the *Arabidopsis* genomic sequence, and the data used in this program have sequence ends at either end. The landmarks located in the regions of flanking gaps and the end sequences of inserts are irregular spots that affect the RLGS analysis. Therefore, the irregular spots are simulated manually and added to the resulting simulation patterns. Finally, the ''AC,'' ''AB,'' and ''AA'' fragments are presented as Vi-RLGS profiles containing sequence information as well as their chromosome location.

To compute the size of each DNA fragment, we used Southern's method in which the reciprocal of mobility (M) plotted against fragment length (L) is linear ($L = 1/M$). This relationship is linear over a wider range than the conventional semilogarithmic plot. In addition, the following equation was adapted to high voltage gradients and the scanning range used in the RLGS method:

$$M = \frac{k_1}{L - k_2} + M_0$$

Where

$$M_0 = \frac{M_3 - M_1 A}{1 - A}$$

$$A = \left\{ \frac{L_1 - L_2}{L_2 - L_3} \right\} \left\{ \frac{M_3 - M_2}{M_2 - M_1} \right\}$$

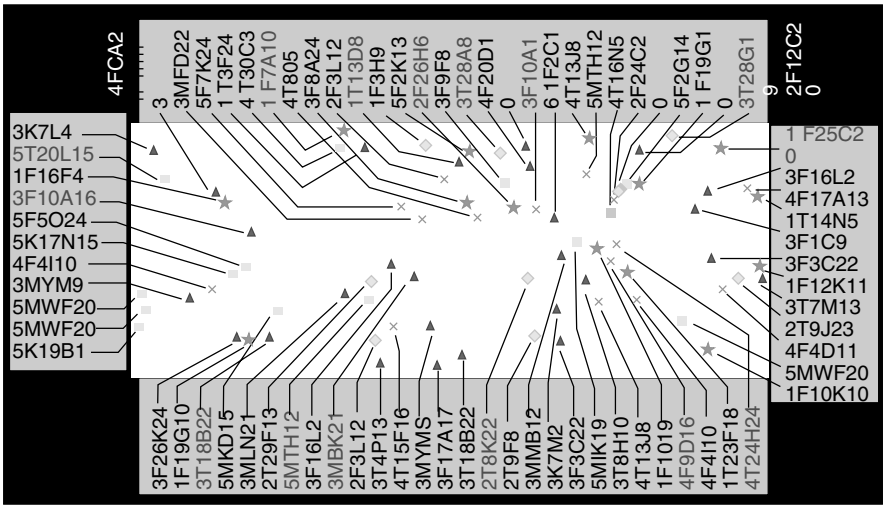
$$k_1 = \frac{L_1 - L_2}{1/(M_1 - M_0) - 1/(M_2 - M_0)}$$

$$k_2 = L_1 - \left\{ \frac{k_1}{M_1 - M_0} \right\}.$$

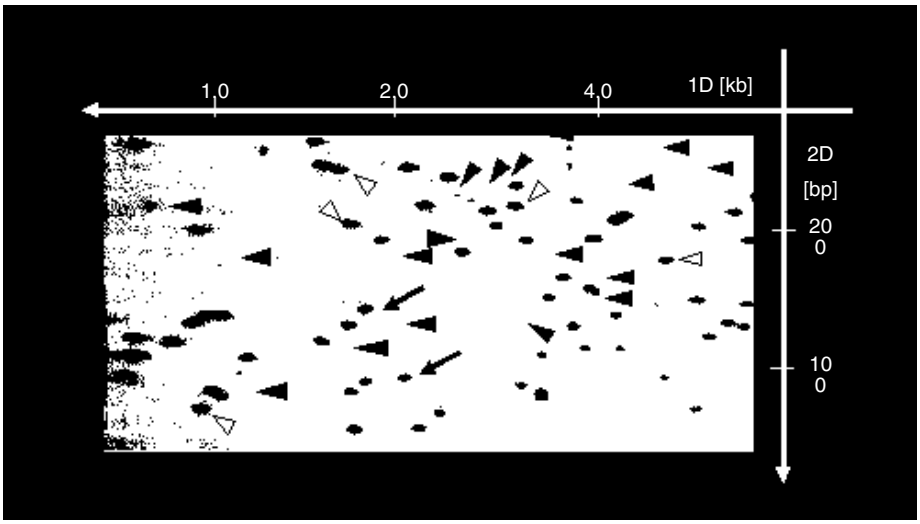
M_0 is a factor calculated to give the best fit to a straight line with the above equation. To calculate M_0, three points, defined by molecular weight standards L_1, L_2, and L_3 and their corresponding mobilities (M_1, M_2, and M_3) were chosen. To provide the precise simulation pattern, three data points were obtained from actual electrophoresis patterns using a

1-kbp ladder marker in a 1st-D 0.8% agarose gel and a 100-bp ladder marker in a 2nd-D 5% polyacrylamide gel, and were substituted for L_{1-3} and M_{1-3} in the above equation. In a preliminary test of this program, a simulated pattern was generated using the entire chloroplast genome sequence for *Arabidopsis thaliana*. *Not*I is used as a universal restriction landmark enzyme in animal and plant RLGS analysis. Here, we performed a *Not*I-*Arabidopsis* simulation profile using our Vi-RLGS system, and *Eco*RV and *Mbo*I were used as enzymes B and C respectively (*Not*I-*Eco*RV-*Mbo*I).

The Vi-RLGS patterns in the range 0.6 to 7.5 kbp in 1st-D and 50 to 300 bp in the 2nd-D are shown in Fig. 18(a), and the real RLGS pattern in the range corresponding to Fig. 18(a) is shown in Fig. 18(b). The two spots indicated by arrows in Fig. 18(b) were cut from the gel and cloned using the previous method. The sequences confirmed that their patterns concurred with the theoretical Vi-RLGS. There is a difference in the number and pattern of spots in Figs. 18(a and b). There are two possible reasons for this difference: (1) there are some gaps in the *Arabidopsis* genomic DNA sequence; specifically, highly repeated sequences, such as centromeres, telomeres, the ribosomal RNA gene clusters, and their flanking regions have not yet been reported; and (2) DNA modification. In plant DNA, 5′-methylcytosine (5MeC) occurs at cytosine residues in symmetrical sequences, such as CpG and CpNpG. In *Arabidopsis* genomic DNA, the 5MeC content (5MeC/5MeC+C) is approximately 5.2%. *Not*I is sensitive to 5MeC, while *Eco*RV and *Mbo*I are insensitive to this methylation. Black arrowheads in Fig. 18(b) indicate spots that are present in Fig. 18(a) and absent or faint in Fig. 18(b). To confirm the influence of 5MeC in *Not*I landmark detection, the spots indicated by arrows in Fig. 18(b) were subjected to a PCR assay. Primers to amplify an approximately 1-kbp sequence containing *Not*I sites were synthesized and *Not*I-digested genomic DNA was amplified. The presence of amplification products indicates that the *Not*I sites are methylated and that the RLGS spot cannot be detected in the real RLGS pattern. Figure 18(c) shows the PCR assay of six spots: 4T16H5, 4F13C5, 2F26H6, 3T28A8, 2F12C20, and 4T24H24. Spots present in the real RLGS pattern, 4T16H5 and 4F13C5 were not amplified, and the masked spots 2F26H6, 3T28A8, 2F12C20, and 4T24H24 were amplified. The amplified DNA fragments were cloned and confirmed to contain *Not*I sites in the target DNA region. In addition, the RLGS pattern of approximately 22%-reduced 5MeC hypomethylated *Arabidopsis* plants generated using AzaC was produced. As a result, some spots present in Fig. 18(a) and absent in Fig. 18(b) were present in RLGS pattern from hypomethylated plants. This means that the masked spots mainly result from DNA methylation. To find spots present in virtual RLGS files and absent in real RLGS patterns requires exhaustive detection of methylated regions in *Arabidopsis* genomic DNA. Owing to the analysis of the difference between Vi-RLGS and the experimentally produced RLGS pattern, the dynamic change of methylation status of genomic DNA can be screened. On the other hand, the yellow arrowheads in Fig. 18(b) are absent or have a slight difference of mobility in the Vi-RLGS profiles. We speculate that they result from gaps in the sequence or from sliding due to methylation in the flanking regions. Nevertheless, the comparison of virtual and real RLGS patterns identified approximately 80% of the spots in the real RLGS pattern based on their



(a)



(b)

Fig. 18 Comparison of the Vi-RLGS profile using nucleic DNA sequences of *A. thaliana* and an experimental RLGS pattern (*Not*I-*Eco*RV-*Mbo*I). (a) Vi-RLGS profile of nuclear genomic DNA. Each spot is given the clone name available at the Web site of The *Arabidopsis* Information Resource (TAIR). Head numbers indicate the chromosome number. Circle (violet): chromosome 1; rhombus (yellow): chromosome 2; triangle (red): chromosome 3; cross (blue): chromosome 4; square (green): chromosome 5. (b) The real RLGS pattern corresponding to the region shown in (a). Black arrowheads indicate spots present only in the Vi-RLGS profile. White arrowheads indicate spots that are absent in the Vi-RLGS profile. (c) PCR assay of seven spots comparing uncut genomic DNA and *Not*I-digested genomic DNA. The marker is *Hinc*II-digested ø174. (d) Vi-RLGS analysis of the mutant. (e) Southern hybridization pattern of control (C) and the mutant (M) digested with *Not*I and *Eco*RV using a clone of the deleted region as the probe. (See color plate p. xxiii.)

Fig. 18 (*Continued*).

pattern and molecular weight as determined by 1st-D and 2nd-D mobility.

Mutations can be induced using physical mutagens, such as X rays, gamma rays, fast neutrons, and ion beams. Since we expect the Vi-RLGS method to be useful for detecting genetic mutations, such as deletions and translocations, we analyzed the RLGS patterns of an X-ray-induced mutant. Figure 18(d) shows that spots 4FCA1 and 4F13C5 are absent in the mutant RLGS pattern. These spots are

linkage markers localized on chromosome IV. In addition, one 4FCA1 spot (centromere side) is present and another is absent in the mutant pattern. These results indicate that a deletion occurred just downstream from 4FCA1. Since spots 4T16H5 and 4T8O5, which are close to 4F13C5, are present in the mutant pattern, this deletion is approximately 2.1 to 2.4 Mbp in size. To confirm the deletion, a clone of the region between 4FCA1 and 4F15C5 was isolated and used as a probe in Southern hybridization (Fig. 18e). The hybridization pattern showed that this region was absent in the mutant genome.

Presently, there are 177 known *Not*I sites in the *Arabidopsis* genome. The Vi-RLGS system revealed that if enzyme B is replaced with another restriction enzyme (excluding *Eco*RV) such as *Dra*I, approximately 88.7% (157/177 spots) of the *Not*I sites will be present in the resolvable scanning field of the *Not*I-*Eco*RV-*Mbo*I and *Not*I-*Dra*I-*Mbo*I patterns. In addition, the average size of a *Not*I fragment of *Arabidopsis* genomic DNA is approximately 706 kbp (125 Mbp = *Arabidopsis* genome size/177). Although some spots are masked by DNA methylation, our *Not*I-*Eco*RV-*Mbo*I profile covers 79.5% of all *Not*I sites, and an Mbp-order deletion is readily detected by the *Not*I-Vi-RLGS profiles. Further Vi-RLGS analysis using various other landmark enzymes will increase the number of effective landmarks and allow more detailed genomic scanning.

Vi-RLGS saves considerable time and labor, and provides a simple procedure for identifying polymorphic spots in RLGS analysis as well as for screening suitable restriction enzymes. In theory, this method is useful for the genomic analysis of organisms with large genomes, even without sequence information for each chromosome. Therefore, the Vi-RLGS system offers a different spectrum of mutation detection than microarrays, and will be a useful tool for detecting mutations in DNA length and modification in forthcoming postgenome sequencing research.

7 Perspective

One of the advantages of RLGS when compared with protein 2-dimensional gels is that the spots of interest can be cloned. The spot cloning technique will expand the application field of RLGS. In fact, a gene whose mRNA transcription is regulated in imprinted manner was cloned using this technique.

The concept of genome scanning arose from the need to survey the genome in the biochemical approach to DNA. Three classic methods that have been previously developed are hybridization-based method, PCR-based method and staining (ethidium bromide)-based method. RLGS is a fourth type based on the novel concept that restriction enzyme sites can be used as landmarks by direct end-labeling, resulting in a variety of specific features and advantages.

The RLGS method had previously been applied to several major research fields, including (1) screening polymorphism, genetic linkage analysis, and positional cloning; (2) cloning of imprinted genes; (3) methylation and genome structure analyses in a tumor or a cloned animal; and (4) discrimination of agricultural crop cultivars.

Analysis of genome modification, such as methylation, is the most important target phenomenon. When the location on

the genome is specified, microarray or PCR techniques can be used. In particular, microarray analysis has enormous capacity to screen many points throughout the genome. However, the whole genome sequence data is the essential prerequisite for the design of the microarray. On the other hand, to screen the genome whose entire sequence has not been analyzed, RLGS is used as it is clear that it is the most rapid system to discover new landmarks because the microarray system can only screen known sites that are printed in a microarray. Even in the screening of a completely sequenced genome, RLGS is very rapid, economical, and convenient for screening the methylation status of genomic DNA because, unlike microarrays, it does not require any special equipment. Thus, RLGS will be a useful method to compliment microarray technology for analyzing whole genome sequence data.

Keywords

Blue–white Selection
Not really selection but color identification. Vectors carrying the β-galactosidase (*lacZ*) gene (or part of it) produce blue plaques in the presence of 5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside (X-gal). If this gene is located in a stuffer fragment, then all recombinants will form white plaques and parental vectors will produce blue plaques in the presence of X-gal.

Genetic Selection
Usually, in cloning, selection against parental, nonrecombinant molecules in favor of the recombinant. For λ-based vectors used for construction of genomic libraries, the two most commonly used types of selection are *Spi* and *supF*. *Spi+* phages carrying *red* and *gam* genes cannot grow in *E. coli* lysogens carrying prophage P2; since, however, the majority of the vectors contain these genes in a stuffer fragment, only recombinant phages can grow in such *E. coli* strains. Selection for *supF* exploits λ vectors carrying amber mutations. These vectors cannot replicate without the *supF* gene, which must be present either in the host or in the cloned insert. If the insert carries the *supF* gene, only recombinant phages will be able to replicate in an *E. coli* host without the suppressor gene.

Polylinker
A short DNA fragment (in the vector) that contains recognition sites for many restriction enzymes, which can be used for cloning DNA fragments into this vector.

Restriction Enzyme
An enzyme that recognizes a specific sequence in DNA and can cut at or near this sequence. In cloning procedures, the most commonly used enzymes produce specific protruding (sticky) ends at the ends of the DNA molecule. Each enzyme produces unique sticky ends. The DNA molecules possessing the same sticky ends can be efficiently joined with the aid of DNA ligase (see ligation).

(STS) Sequence-tagged Site
A short (200–500 bp) sequenced fragment of genomic DNA that can be specifically amplified using PCR. STS represents or is linked to some kind of marker (i.e. it is mapped to a specific locus on a chromosome).

By virtue of the powerful technology developed in molecular biology, it is possible to isolate any DNA fragment in the genome of an organism and, after reverse transcription, any transcribed gene in the form of a complementary DNA. The isolation (cloning) procedure involves the insertion of the DNA fragment into a vector, capable of replication in a microorganism, which allows production of large quantities of the DNA fragment for physical or biological analysis. Upon determination of the location in the genome from which the particular DNA

fragment was derived, that fragment acquires the property of a DNA marker. Such DNA markers are a prerequisite for physical and genetic mapping of the genome of the organism. DNA markers are also of importance for the diagnosis of genetic diseases. DNA markers can be divided into several different classes depending on the way in which the markers were selected among the fragments of genomic DNA. Examples of such classes are anonymous, micro- and minisatellites, restriction fragment length polymorphism (RFLP) markers, and *Not*I linking clones.

Vectors and clone libraries of different types can be used to clone markers. Lambda-based vectors and genomic libraries of different kinds are commonly used for this purpose. Many different variants of λ-based vectors that combine features of different cloning vehicles (plasmids, M13 and P1 phages) have been created for this purpose. The use of each vector is usually limited to a specific task: the construction of general genomic libraries (which contain all genomic DNA fragments) or special genomic libraries (which contain only a particular subset of genomic DNA fragments). Among these special libraries, *Not*I linking and jumping libraries have particular value for physical/genetic mapping and sequencing of the human genome. Shotgun and slalom libraries are usually used for sequencing purpose and comparative genomics.

1 Principles

In molecular biology, ''cloning'' is the insertion of DNA with interesting information into a specific vector that allows replication and transfer of the cloned DNA from one host to another. The vector containing the inserted DNA is called a *recombinant vector* to distinguish it from its parental vector, which does not contain any foreign DNA. Usually, ''interesting information'' is a piece of DNA obtained from any target organism; it can be a gene (or part of a gene) or simply anonymous DNA sequences for which no function is yet known. It can originate directly from DNA or can be obtained from reverse transcription of RNA molecules. The main idea of cloning is to obtain the interesting piece of DNA in a quantity large enough for analysis and further experiments. Now, the vectors and strategies used for cloning come in many different types. This chapter concentrates on the widely used λ-based vectors and the construction of genomic libraries, which played an important role in the Human Genome Project.

A genomic library is a collection of recombinant vectors; it contains DNA fragments representing the genome of a particular organism. Genomic libraries can be either general, containing DNA fragments covering the whole genome, or special, containing only specific genomic fragments that differ in certain parameters. Some are CG rich whereas others contain only particular size fragments of DNA obtained after digestion with a particular restriction enzyme, contain specific repeats, and so on. Important special genomic libraries are the jumping and linking types (see Sect. 2.3).

Cloned DNA fragments can be located to a specific site of a chromosome, after which they can serve as markers for physical and genetic mapping. Different types of markers are used. The so-called

anonymous markers represent randomly cloned DNA fragments whose functions or specific features are not known. Other DNA markers can possess specific features. They can contain a known gene or expressed sequences with unknown function, CpG islands (also associated with genes, see Sect. 3.2), or recognition sites for rare cutting restriction enzymes convenient for long-range mapping. Such markers can be polymorphic, that is, they have different structures in different individuals (they are usually distinguished on the basis of different mobility in gel electrophoresis). Such markers are extremely important in mapping and cloning human disease genes and for construction of genetic maps. Three types of polymorphic markers are commonly used (Fig. 1).

Single-nucleotide polymorphism (SNP) markers are DNA fragments that have a point mutation in some individuals of a population. The advantages of SNPs are their abundant numbers ($>10^6$) and the fact that they can be detected by nonelectrophoretic methods, for example, using microarrays. However, usually SNP has only two alleles. A subtype of SNPs are RFLP markers that recognize genomic fragments containing polymorphic recognition sites for a particular restriction endonuclease (e.g. *Taq*I, *Msp*I). The same chromosomal regions in different individuals contain or lack this recognition site.

A second form of DNA polymorphism results from variation in the number of tandemly repeated (VNTR) DNA sequences in a particular locus. Usually, they are divided in two types – mini- and microsatellites. Minisatellites are DNA fragments 0.1 to 20 kb long that contain many copies (from 3 to more than 40) of

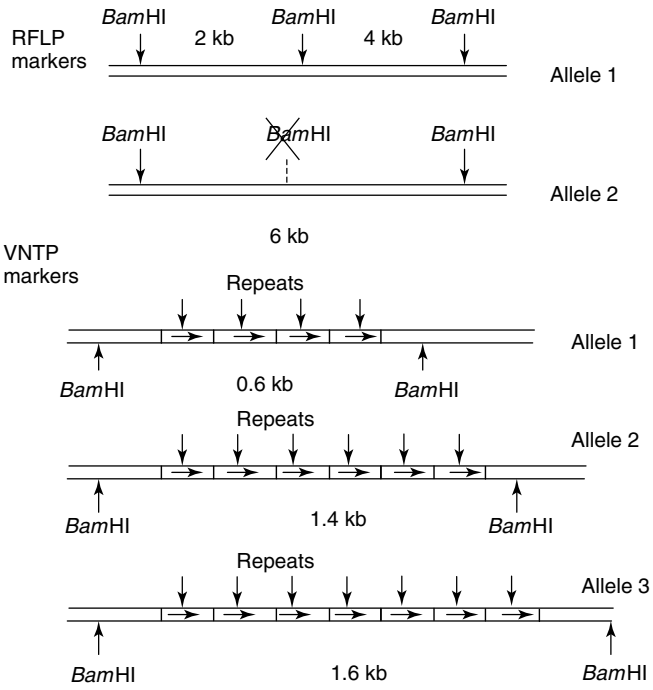

Fig. 1 The difference between RFLP and VNTR polymorphism.

6 to 60 bp repeats. All these repeats share a 10 to 15 bp core sequence similar to the generalized recombination signal (*chi*) of *E. coli*. When DNA from different individuals is digested with a restriction enzyme that does not cut inside these repeats, the length of the fragments produced will depend on the number of repeats at the locus. Since the minisatellites and repeats constitute a relatively large fragment, it is possible to discriminate between different alleles using ordinary nondenaturing gel electrophoresis and Southern blot analysis. Many different alleles (usually more than five) can be distinguished at a locus containing minisatellites. Minisatellites cluster around the distal ends of human chromosomes and, sometimes, are located near the genes.

Microsatellites are relatively short DNA fragments (usually <100 bp) with repeat units from 1 to 5 bp (such as A, AC, AG, AAC, AAAG, etc.). They are numerous (5×10^5) and uniformly distributed throughout the human genome with an estimated average spacing of about 6 kb.

Microsatellites can be very polymorphic (more than 10 alleles at the same locus), and polymorphism usually increases with the number of repeats. Microsatellites with fewer than 10 copies are usually not polymorphic. Since microsatellites are short, they can be analyzed quickly by using the polymerase chain reaction (PCR) with primers flanking each locus. Different alleles can be resolved using denaturing gel electrophoresis. Very frequently, microsatellites are associated with Alu repeats (see Sect. 3.1) and this creates problems for their use with PCR, since Alu repeats are conserved in the human genome. Thus, flanking primers for the microsatellite located in the Alu repeat are unlikely to be useful because they prime from many Alu repeats and, instead of discrete bands, give a smear after electrophoretic separation of the PCR products.

An optimal marker should have the features of all the different types of markers just discussed. The ideal marker should contain (1) a gene, (2) a CpG island that has been shown to be very conserved in the genome and can be used for comparative gene mapping in different species, (3) a rare cutting restriction site useful for physical mapping, and (4) polymorphic sequences (e.g. microsatellites). One of the best candidates for having all these features together is *Not*I linking clones, that is, recombinant clones containing the *Not*I restriction site.

2 Techniques

2.1 General Characteristics of λ-based Vectors Used for Construction of Genomic Libraries

Among other more modern vectors used for construction of genomic libraries (yeast, bacterial and P1 artificial chromosomes; YAC, BAC, and PAC respectively), phage λ-based vectors are still very popular. The reason is that the genetics and features of both λ phage and *E. coli* (the host for λ phage) are well known. The size of the phage DNA that can be packaged into viable phage particles is limited between 37.7 and 52.9 kb. This means that it is possible to biologically regulate the size range of the cloned DNA fragment. There exist extremely efficient *in vitro* systems for packaging such DNA into λ phage particles (10^9 plaque-forming units per μg of DNA) to produce viable phages. To combine the features of different vector systems, extensive modifications of λ phage vectors were developed (Fig. 2).

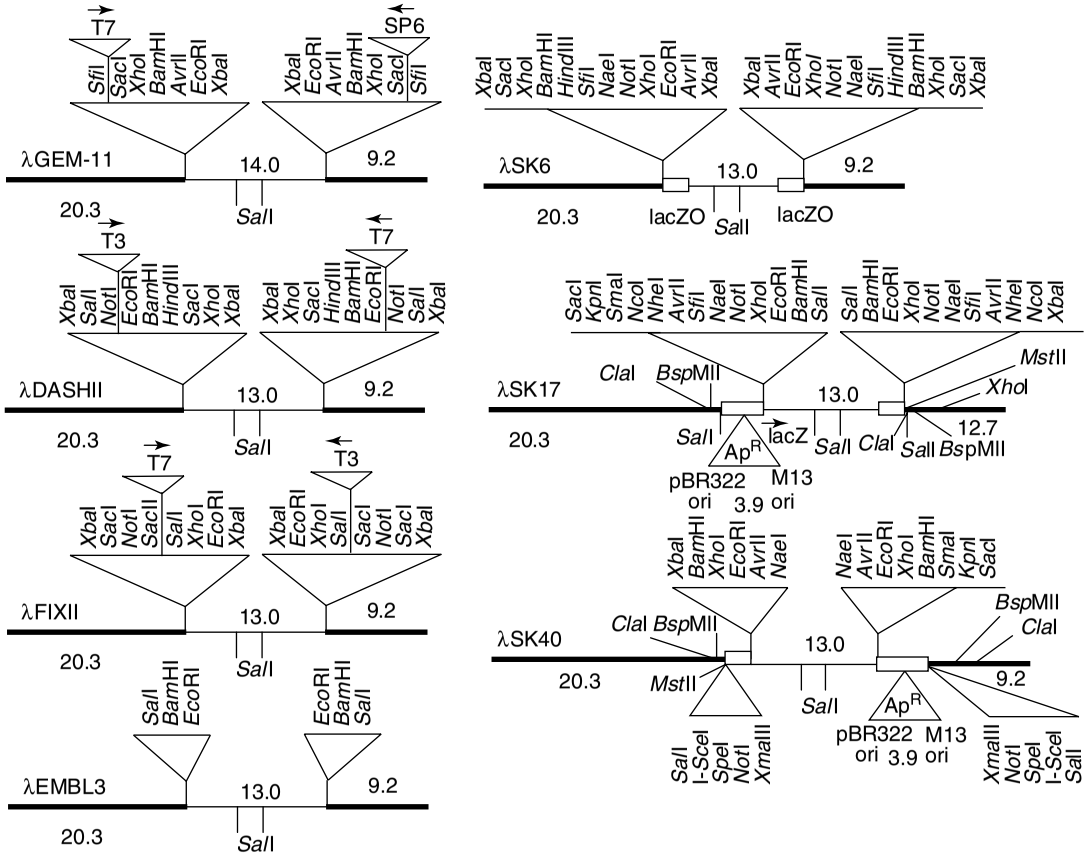

Fig. 2 Examples of λ-based vectors: standard λ vectors (λGEM11, λFIXII, λDASH, λEMBL3, λSK6) and diphasmid vectors (λSK17 and λSK40). Sizes are in kilobases. Not all restriction sites are shown. Heavy lines represent vector arms, thin lines denote the stuffer fragment; open boxes mark plasmid and M13 sequences; *lacZO* is the *lac* operator sequence. T3, T7, SP6 – promoters for T3, T7, and SP6 RNA polymerases.

Cosmids are essentially plasmids that contain the *cos* region of phage λ responsible for packaging of DNA into the phage particle. The advantages of cosmids are easy handling (as with plasmids) and large cloning capacity. Since the plasmid body is usually small (3–6 kb), large DNA molecules (46–49 kb) can be cloned in these vectors.

Phasmids are λ phages that have an inserted plasmid. They have the same basic features as λ phage vectors, but the inserted foreign DNA fragment can be separated from the body of the phage DNA and converted into the plasmid form. After the conversion, the cloned DNA fragment will exist as a recombinant plasmid.

Hyphages represent another type of λ-based vectors. They were constructed from M13 vectors with a built-in *cos* site of λ. Since these vectors have the main features of M13 vectors, they can be obtained in single-stranded form. Their distinctive feature is the capability to be packaged with high efficiency into λ-phage-like particles. This decreases the chance of recovering nonrecombinant vectors and opens the possibility of constructing a representative genomic library in single-stranded form.

Diphasmids are vectors, which offer the opportunity to combine the advantages of phages (λ and M13) and plasmids. Diphasmids can be divided into two classes: those that can replicate as phage λ (an improvement over phasmids) and those that are incapable of replicating as phage λ (i.e. a cosmid capable of being packaged into phage M13 particles).

In some cases, it is more convenient to work with a genomic library in plasmid than in λ phage form. The construction of a representative genomic library directly in a plasmid vector has several drawbacks and difficulties. However, all these problems can be easily solved with the help of phasmid and diphasmid vectors. Often a genomic library is constructed in a λ phage and then converted in its entirety to plasmid form.

2.2 Construction of General Genomic Libraries

Representativity is one of the most important features of a genomic library. In a "representative" genomic library, every genomic DNA fragment will be present in at least one of the recombinant phages of the library. In practice, however, this is difficult to achieve. Some genomic fragments are not clonable because of the strategy used for construction of the genomic library. For example, if the maximal cloning capacity of the vector is 18 kb and *Eco*RI digestion is used to construct the library, no genomic *Eco*RI fragments bigger than 18 kb will be present. In some cases, genomic DNA fragments can suppress the growth of the vector or the host cell, with the result that its cloning can be restricted to specific vector systems.

The important reason for decreased representativity is the different replication potential of different recombinant phages. Most researchers work with amplified libraries. The ligated DNA molecules are packaged into the λ phage particles and plated on a lawn of *E. coli* cells (usually many petri dishes are used for such plating). Then all λ phage particles are eluted from the plaques, and the liquid eluted from all the petri dishes is mixed. Glycerol or dimethyl sulfoxide is added to the eluate, and the aliquots are kept at – 76 °C. This procedure is called *amplification* of the library.

With amplification, a library can be kept for many years and can be used for many experiments by many researchers. On the other hand, each recombinant phage present in the library gives a single plaque

at the first plating, and since different recombinant phages differ in their growth potential, there may be differences of 100 times in the abundance of clones after amplification. This means that in the amplified library, some of the phages are present 100 times more often than others. In this case, to recover all recombinant phages obtained after packaging into λ phage particles, one needs to plate 100 times more phages than that obtained after the original plating. Since such quantities are difficult to achieve in practice, some recombinant phages are virtually lost from the library after amplification.

How is the representativity of a library estimated? A library is considered to be representative if after the first plating (before amplification) it contains a number of recombinant clones together, containing genomic DNA fragments equal to 7 to 10 genome equivalents. For example, human genomic DNA contains approximately 3×10^9 bp. If the vector contains on an average 15 kb inserts, the representative library should contain 1.4 to 2.0×10^6 recombinant clones.

The way in which the genomic DNA fragments are produced for cloning is also important. The more randomly the genomic DNA is broken, the more representative a library can be obtained. Clearly, the *Eco*RI enzyme (6 bp recognition site) will cut genomic DNA less randomly than *Sau*3AI (4 bp recognition). Probably, the shearing of DNA molecules using physical methods (e.g. syringe, sonication) is the most reliable way to obtain randomly broken DNA molecules.

An important characteristic feature of a library is the percentage of recombinants. For most purposes, if a library contains more than 80% of recombinant phages, it is better to omit the genetic selection procedure because it usually decreases the representativity of the library. To calculate the percentage of recombinants, one can use genetic (*Spi*) selection as in the case of λEMBL vectors. Another approach relies on blue–white color identification (e.g. λ-Charon series). A third class of vectors has both genetic selection and blue–white color identification (λSK4, λSK6). There are three commonly used ways to construct genomic libraries (Table 1, Fig. 3).

The original (''classical'') method includes generation of sheared genomic DNA fragments using physical or enzymatic manipulations followed by the physical separation of fragments of a particular size using, for example, ultracentrifugation or gel electrophoresis. The vector DNA is digested with two (or even three) restriction enzymes whose recognition sites are located in the polylinker and are separated by a few base pairs. The arms and the stuffer piece are purified from the small oligonucleotide molecules released after the digestion by, for example, precipitation with polyethylene glycol (PEG) 6000. The stuffer piece and both arms will now have different sticky ends, preventing re-creation of the original vector molecules during subsequent ligation with genomic DNA fragments.

In the second ''dephosphorylation'' approach, the phage arms are prepared by simultaneous digestion with two restriction enzymes as shown earlier. Genomic DNA is partially digested to the extent that DNA fragments with sizes in the range of 15 to 20 kb will represent the majority of the products. These DNA fragments are dephosphorylated to prevent their ligation to each other and are then ligated to the vector arms. If too big or too small genomic DNA fragments are ligated to the phage arms, size limitations will make it impossible for these recombinant molecules to yield viable phages. Compared to the preceding

Tab. 1 Comparison of three basic methods used in construction of representative genomic libraries.

Method	*DNA [µg] needed to construct a representative genomic library*	*DNA fractionation*	*Self-ligation of*		*Effectiveness of packaging*		*Number of packaging reactions to get representative library at maximal efficiency per microgram of genomic DNA*	*Genetic selection necessary to remove nonrecombinants*
			vector DNA	*genomic DNA*	*Per microgram of vector DNA*	*Per microgram of genomic DNA*

method, this procedure is quick, and representative libraries can be obtained from a small quantity of genomic DNA.

The third "partial filling-in" method, also avoids fractionation steps (Fig. 3). Phage arms are prepared as described before (in this particular case *Sal*I and *Eco*RI are shown, but many other combinations can be used), and the sticky ends produced are partially filled in with the Klenow fragment of DNA polymerase I (or other DNA polymerase) in the presence of dTTP and dCTP. Genomic DNA partially digested with *Sau*3AI is also partially filled in, but in the presence of dATP and dGTP. Under such conditions, self-ligation of vector arms or genomic DNA is impossible.

Genomic libraries can be constructed in cosmids using the same approaches just described. The absence of selection against nonrecombinant vector and the possibility of packaging into phage particles concatemers composed solely of cosmid fragments make it even more important to prevent self-ligation of vector fragments. Many similar approaches have been suggested and one of them is shown in (Fig. 4) where the formation of vector-concatemers is prevented by partial filling in.

A similar effect can be achieved by dephosphorylation or by digestion at the first step with *Acc*I and *Sma*I instead of *Eco*RI and *Hind*III. *Sma*I produces blunt ends and *Acc*I gives sticky ends with only two protruding base pairs. The ligation of these ends will be far less effective than that for *Bam*HI and *Sau*3AI sticky ends (four protruding base pairs).

2.3 Construction of Jumping and Linking Libraries. Use of Linking and Jumping Clones to Construct a Physical Chromosome Map

For long-range mapping and cloning of large stretches of genomic DNA, the

two most widely used methods are construction of overlapping DNA sequences (contigs) using chromosome walking (e.g. BAC cloning) and chromosome jumping. The technique of BAC cloning is now used by many laboratories. Still, this approach is not devoid of problems and drawbacks. These problems could be diminished, however, by using jumping/linking libraries. Moreover, jumping and linking libraries can be used independently for construction of a long-range restriction map using pulsed field gel electrophoresis (PFGE). Jumping clones contain DNA sequences adjacent to neighboring *Not*I sites, and linking clones contain DNA sequences surrounding the same restriction site.

The two best-known kinds of jumping libraries are the *Not*I jumping library and the ''general'' jumping (hopping) library. The basic principle of both methods is to clone only the ends of large DNA fragments rather than continuous DNA segments, as in BAC clones. Internal DNA is deleted by controlled biochemical techniques. The main difference is that in the first type of library, complete digestion with a rare cutting enzyme (*Not*I is the most popular) is used, and the second is based on a partial digestion with a frequently cutting enzyme, followed by isolation of DNA fragments of desired size. Using the first type of library, it is possible to jump over long distances (>1000 kb), but only from certain starting points (i.e. those containing the recognition site for the rare cutting enzyme). Using the hopping library, it is possible to start jumping from practically any point and to cover a defined but shorter distance (<150 kb). Only the first type of jumping libraries can be used in conjunction with linking libraries to create genomic maps, as described next.

There are two main approaches for the construction of *Not*I jumping and linking libraries. According to the first method (Fig. 5a), jumping libraries are constructed as follows: DNA of high molecular mass, isolated in low-melting agarose, is completely digested with *Not*I.

The DNA is ligated at very low concentration, in the presence of a dephosphorylated plasmid containing a marker (*supF* gene), and is then circularized, trapping the *supF* gene, which acts like a marker to select clones that contain the ends of a long fragment. Another enzyme, one that has no recognition site in the plasmid, is used to digest the large circular molecules into small fragments, each of which is cloned in a vector phage carrying amber mutations. Recombinant phages containing the plasmid with the two terminal fragments are selected in an *E. coli* strain lacking the suppressor gene.

The linking library can be constructed in different ways. In the original protocol, the genomic DNA is partially digested with *Sau*3A and size selected to obtain 10 to 20 kb fragments. The DNA is then diluted and circularized in the presence of *supF* marker plasmid. The circular products are digested with *Not*I, ligated into a *Not*I-digested suppressor-dependent vector (NotEMBL3A), and plated on a suppressor-negative host.

In another approach, DNA from a total genomic library in a circular form (e.g. cosmid) is digested with *Not*I, and a selectable marker (e.g. resistance to the antibiotic) is inserted into recombinants containing this site. Then these recombinants are selected by their resistance to the antibiotic.

The most important drawback is that all these methods used to construct linking libraries exploit strategies and vectors different from those used to construct jumping libraries. Thus, some fragments

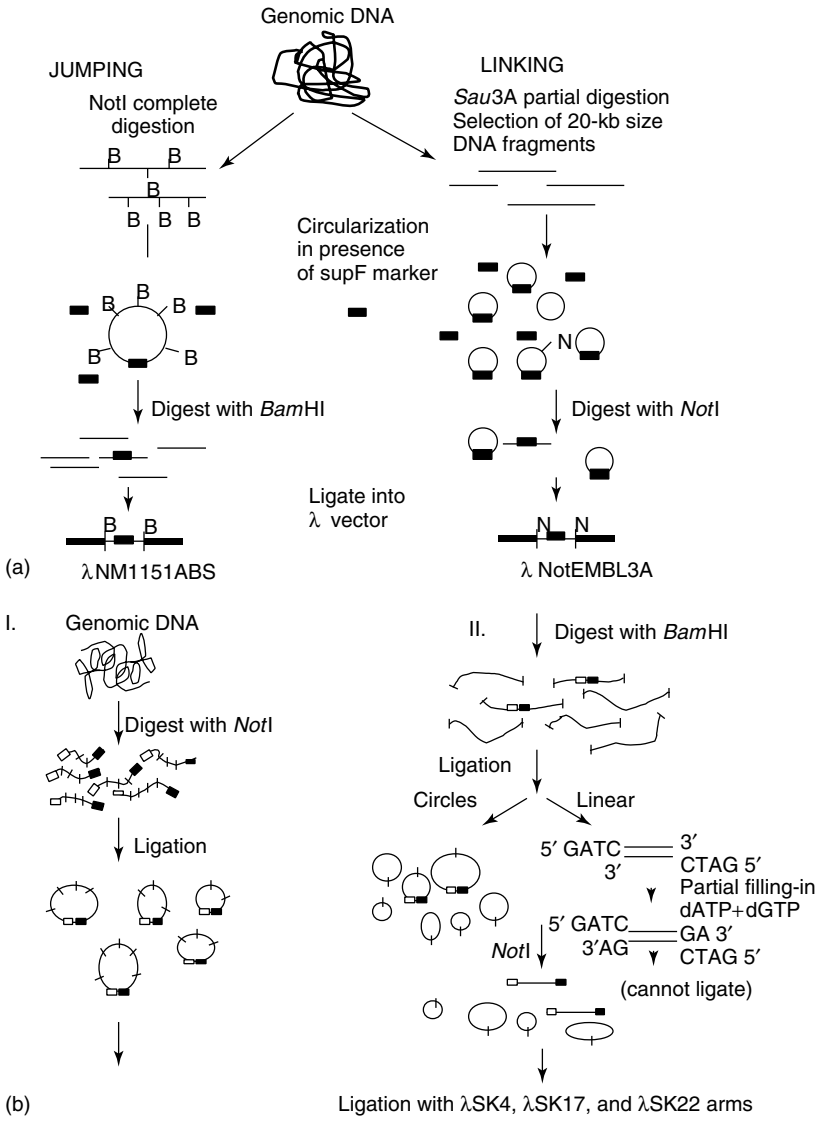

Fig. 5 Two approaches for the construction of jumping and linking libraries: (a) using *supF* marker and (b) using partial filling in. (a) Black boxes, *supF* marker; B, *Bam*HI. (b) Black and white bars denote *Not*I sites and vertical slashes represent *Bam*HI sites; (b I), (b II), construction of the jumping library; (b II), construction of the linking library. In this case, digestion of the genomic DNA with *Bam*HI is the first step.

present in one library (e.g. jumping) will be absent in another (e.g. linking), which creates serious problems for the use of these libraries in mapping.

An integrated approach for construction of jumping and linking libraries is outlined in Fig. 5(b). The most important feature here is that the same vectors and

protocol are used for construction of both libraries.

For the linking library, genomic DNA is completely digested with *Bam*HI. Subsequently, the DNA is self-ligated at a very low concentration (without a *supF* marker) to yield circular molecules as the main product. To eliminate any linear molecules, the sticky ends are partly filled in with the Klenow fragment in the presence of dATP and dGTP. Since the Klenow fragment also has exonuclease activity, all the *Bam*HI sticky ends are neutralized and nearly all ends generated upon random DNA breakage become unavailable for ligation. Subsequently, the DNA is cut with *Not*I and cloned in λSK4, λSK17, and λSK22 vectors.

The same strategy is applied in the construction of a *Not*I jumping library. One initial step is added: genomic DNA is fully digested with *Not*I and self-ligated at a very low concentration. The subsequent steps are the same as for the linking library. An obvious difference between this approach and the preceding ones is that the procedure combines a biochemical selection for *Not*I jumping fragments with improved ligation kinetics during the preparation of the libraries (see Table 2 for a comparison of two methods).

In theory, a linking library is sufficient to construct a physical chromosomal map. When linking clones are used to probe a PFGE genomic blot (*Not*I-digested genomic DNA), each clone should reveal two DNA fragments, which are adjacent in the genome. Thus, in principle, one should be able to order the rare cutting sites with just a single library and one digest, although it will generally not be possible to distinguish between two fragments of the same size. To resolve such ambiguities, it is important to use several different libraries, each for a particular enzyme, and to overlap the resulting patterns just as in ordinary restriction

Tab. 2 Comparison of two main methods for construction of *Not* I jumping libraries.

Method I (with supF marker)	***Method II (with partial filling in)***
Materials required for construction of jumping library	
2 μg genomic DNA (10 mL ligation volume)	1 μg genomic DNA (5 mL ligation volume)
40 μg vector arms	1 μg vector arms
500 μL-sonicated extract (SE) for *in vitro* packaging	15 μL SE
2000 μL freeze-thaw extract for *in vitro* packaging (FTL)	10 μL FTL
Cloning capacity	
0–12 kb	0.2–23 kb
Expected yield	
$1–5 \times 10^4$/μg genomic DNA	$1–5 \times 10^5$/μg genomic DNA
Percentage of recombinants before genetic selection	
<1%	45–60%
Maximum sizes of jumps	
450 kb	>1000 kb

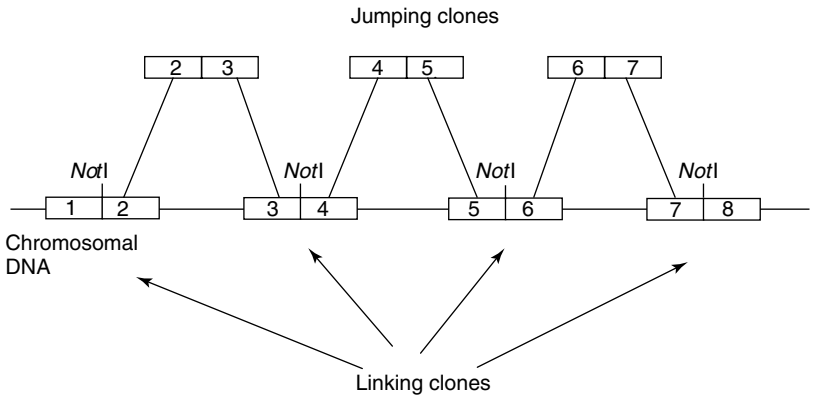

Fig. 6 Long-range mapping using jumping and linking libraries.

fragment analysis. To accomplish this for the whole human genome will be very laborious. However, for small stretches of the genome containing 5 to 10 *Not*I sites, this approach can be efficient. The use of jumping and linking libraries in a complementary fashion simplifies this approach (Fig. 6).

Moreover, by cross-screening the two libraries, it should be possible in principle to jump from clone to clone (–jumping–linking–jumping, etc.), to generate an ordered map without using PFGE techniques at all. One of the main problems with this approach is that the presence of very CG-rich regions and repeats in the human DNA may result in cross-hybridization between different clones.

In the shotgun sequencing approach for long-range genome mapping, the hybridization technique is replaced by sequencing. Jumping and linking clones are sequenced from the ends and, subsequently, the linear order of the *Not*I clones on a chromosome can be established using a computer program. Even a 20 bp sequence is likely to uniquely identify a sequence in the human genome. The sequence data provide a means to discriminate even between different instances of the same class of repeats.

3
Applications and Perspectives

3.1
Cloning DNA Markers Specific for a Particular Chromosome

It is important, for many purposes, to clone individual DNA markers for a specific chromosome. The most straightforward approach for such purposes is to prepare special libraries that contain recombinant clones from a particular chromosome. One approach is based on the use of the fluorescence-activated cell sorter (FACS) system. FACS operates on the principle of rapid analysis of suspended particles, single cells, or even chromosomes. A suspension of chromosomes stained with fluorescent dyes (usually Hoechst 33258 and chromomycin A3) passes through the focus of a laser beam that excites the DNA-bound fluorescent dyes. Equal-sized droplets are formed by ultrasonic dispersion, and the droplets containing the desired chromosome as indicated by the

fluorescence measurement are deflected from the main stream by an electric field and collected in a tube. DNA isolated from sorted chromosomes can be used for construction of genomic libraries.

Another approach is based on the use of hybrid cell lines. To obtain such somatic cell hybrids, human cells are fused with rodent cells (e.g. mouse or hamster). When the resulting hybrid cells are grown in culture, there is a progressive loss of human chromosomes until only one or a few of them are left. At this step, some of the segregant hybrid cells can be quite stable. In a modification of this technique, a human cell line is transfected with a plasmid vector or infected with a retroviral vector that contains a selectable marker (e.g. *gpt* or *neo*). Transfected clones are screened for those that contain only a single integrated plasmid per cell (and thus containing a single marked chromosome). These transformants are micronucleated by prolonged colcemid treatment and the microcells, containing only one chromosome, are produced using special techniques. The microcells are fused to mouse cells, and the resulting human–mouse microcell hybrids, containing the single marked chromosome, are isolated by growth in selective medium. Hybrid cells containing only fragments of human chromosomes can be produced using human chromosomes with translocations and deletions, or the fragments can be produced experimentally by X-irradiation (radiation hybrids). Such hybrid cell lines are very useful not only for constructing genomic libraries but also for physical mapping of already isolated DNA markers and genes. Another advantage of somatic hybrid cells is that DNA is available in large amounts and can be used for different purposes. Human-specific clones can be isolated from the library by hybridization to total human DNA.

At least 40% of the human genome consists of repetitive sequences of different kinds. Among them, about 50% are repeats randomly distributed in the human genome – different kinds of short (SINE) and long (LINE) interspersed (repeating) elements. The most abundant among them is the Alu repeat family. Alu repeats are present at $>1.0 \times 10^6$ copies per genome with an estimated average spacing of about 3 kb. Alu repeats have a length of about 300 bp and consist of 2 homologous units. Related repeats also exist in other mammals. Different members of this family from the same species usually have homology of 80 to 90% but are only about 50% identical in different species. These repeats have conserved and variable regions. It is possible to find conserved sequences that are species-specific. These conserved sequences can be used as primers for PCR, to specifically amplify human sequences in the presence of nonhuman DNA. These features are the basis for using Alu repeats for isolation of human chromosome–specific sequences from hybrid cell lines containing human and nonhuman DNA sequences. Moreover, if a hybrid cell line contains only a short piece of human chromosome, the Alu-PCR approach can be used for isolation of markers specific for a defined region of the chromosome. The principles of the approach are shown in Fig. 7.

In the case of two hybrid cell lines, one containing a complete human chromosome (HCL1) and the other carrying the same chromosome but with a deletion (HCL2), this method offers the possibility of obtaining markers specific for the deletion. This variant can be called the differential Alu-PCR approach for obtaining

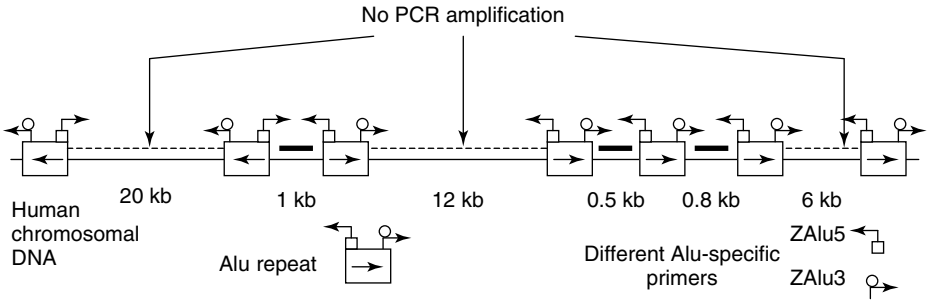

Fig. 7 General scheme for Alu-PCR.

DNA markers. The approach is mainly used in two variants.

In one variant, Alu-PCR is done using DNA from both cell lines, and the products of the reactions are separated by agarose gel electrophoresis. Some bands present in the products from HCL1 will be absent among the products from HCL2. These bands can be excised and cloned, giving markers localized in the deletion. The disadvantage of this approach is that usually such Alu-PCR results in a large number of products that have a very complex pattern and look like a smear on the gel. Among the solutions to this problem that have been suggested is the use of more specific primers (only for a subset of the Alu repeats), or genomic DNA digested with restriction enzyme. Another solution is to use hybrid cell lines that contain only small pieces of human chromosomes.

The second variant of the Alu-PCR approach is mainly used in connection with sources that contain only a limited amount of human material: YAC clones and radiation hybrid cell lines containing small pieces of the human chromosomes. The YACs can, for example, be used for Alu-PCR and the total products of the PCR reaction can be used as a probe to screen genomic libraries (e.g. in cosmids). The hybridization pattern reveals which cosmids are present in one YAC, which in other YACs, and which are present in one but absent in another. Such an approach is also useful for mapping.

Another approach to obtaining region-specific libraries is to use chromosome microdissection to physically remove the chromosomal region of interest; the minute quantities of microdissected DNA can be subjected to a microcloning procedure. Spreads of human chromosomes are made and stained using standard cytogenetic techniques. DNA from an individual band is then cut from the chromosome using ultrafine glass needles or is isolated with the help of laser equipment. In the latter case, all other chromosomes are destroyed by the laser, and intact DNA is present only in the chromosome of interest. DNA obtained from only a few (2–20) chromosomes is enough for constructing a region-specific library. This DNA is amplified using PCR and cloned in plasmid or λ vectors.

3.2 CpG Islands as Powerful Markers for Genome Mapping; CpG Islands and Functional Genes

Although human DNA is highly methylated, stably unmethylated sequences (about 1% of the genome) have been

observed in human chromosomal DNA. Such sequences occur as discrete "islands," usually 1 to 2 kb long, that are dispersed in the genome. They are usually called *CpG (rich) islands* because they contain more than 50% of CG (human genome contains, on average, about 40% of CG contents). Their distinctive feature is the presence of CpG pairs at a predicted frequency, whereas elsewhere in the genome, it is present at a frequency less than 25%. Altogether, there are about 30 000 islands in the haploid genome (the average spacing is about 1 per 100 kb). It is now clear that the majority (if not all) of CpG islands are associated with genes. It has been shown that recognition sites for many of the rare cutting enzymes are closely associated with CpG islands. For example, at least 82% of all *Not*I and 76% of all *Xma*III sites are located in the CpG islands. More than 20% of CpG-island-containing genes have at least one *Not*I site in their sequence, while about 65% of these genes have *Xma*III site(s).

3.3 Alu-PCR and Subtractive Procedures to Clone CpG Islands from Defined Regions of Chromosomes

The Alu-PCR approach is used successfully for cloning DNA markers, but it does result in cloning small DNA fragments (500 bp) between Alu sequences. Alu sequences are distributed in a random fashion and are not linked with genes or other markers. An obvious suggestion for making Alu-PCR more useful for mapping is to use not simply genomic DNA from different sources but linking libraries constructed from these sources. This modification has certain advantages: using isolated probes, it is easy to clone a parental linking clone (e.g. *Not*I), which is a natural marker on the chromosome, convenient for linkage with other markers. Furthermore, linking clones are located in CpG-rich islands that are associated with genes. According to this scheme, linking libraries are constructed from different hybrid cell lines containing either whole or deleted human chromosomes. Then, total DNA isolated from these libraries can be used for Alu-PCR in the manner described in Sect. 3.1. However, in this case every PCR product (either discrete bands or total product) is used as a probe to isolate linking clones from the defined region of the chromosomes.

Genomic subtractive methods represent potentially powerful tools for identification of deleted sequences and cloning region–specific markers. This approach has given rewarding results in less-complex systems such as yeast or cDNA libraries, but the great complexity of the human genome has generated serious problems. These problems can be overcome by reducing the complexity of the human genomic sequences. Two approaches have been suggested to achieve this aim. In one (representational difference analysis), only a subset of genomic sequences (e.g. *Bam*HI fragments less then 1 kb) is used for subtractive procedures; this approach will result in cloning of random sequences. In the other, *Not*I linking libraries are used instead of whole genomic DNA. Intermediate products, that is, circles after the first ligation step can also be successfully utilized for subtraction (Fig. 8).

The *Not*I linking library is at least 100 times lower in complexity than the whole human genome. It is approximately equal in complexity to the yeast genome. Since this approach is not linked with Alu repeats, it offers the possibility of isolating *Not*I linking clones that are unavailable for cloning using Alu-PCR.

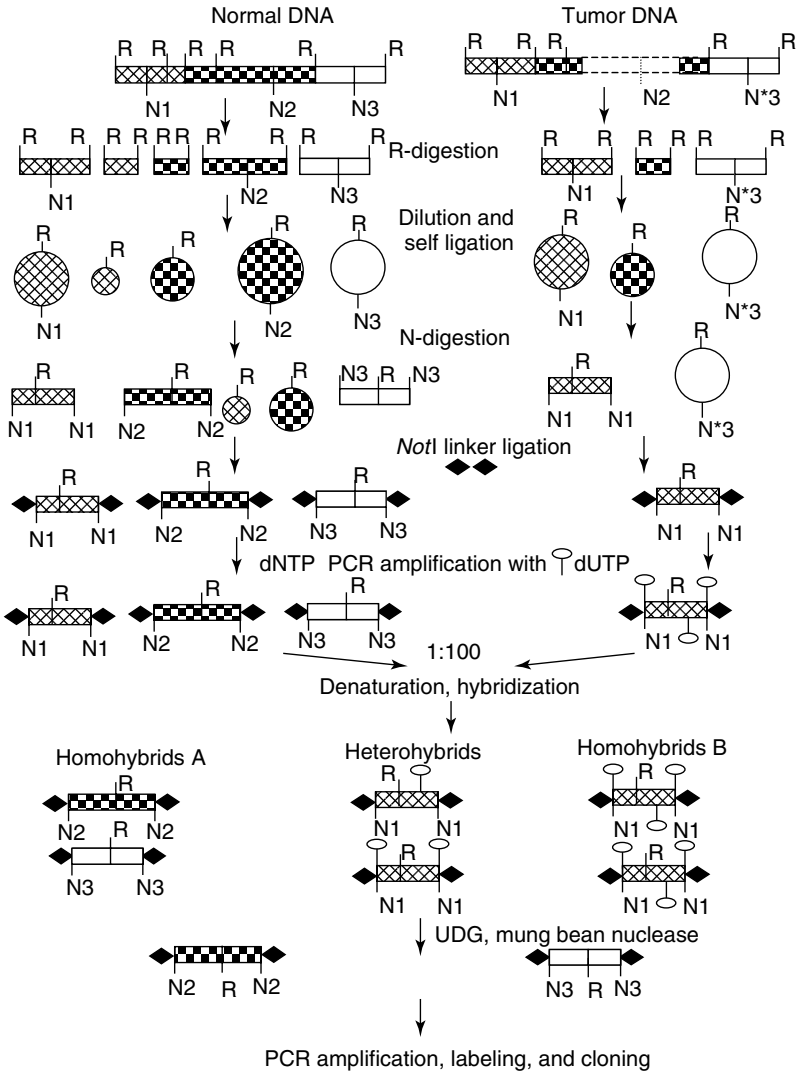

Fig. 8 General scheme for the *Not*I-CODE (Cloning *O*f *DE*leted_ sequences) procedure. N, *Not*I sites; R, restriction enzymes recognizing a 4 to 6 bp sequence. Methylated *Not*I site is indicated by an asterisk. UDG, uracil-DNA glycosylase destroys all DNA molecules containing dUTP. Mung bean nuclease digests double-stranded DNA with mismatches and all single-stranded molecules. Circles digested with *Not*I and PCR-amplified are called NR, *Not*I representation, because only sequences surrounding *Not*I sites are present in this amplification product. The N2 site is deleted and the N*3 site is methylated in tumor DNA.

3.4 IBD (Identical-by-descent) Fragments for Identification of Disease Genes

Development of the methods permitting cloning of identical sequences (CIS) between two sources of DNA can be very useful for many purposes, including isolation of disease genes. Identical-by-descent(IBD) sequences refer to segments of the human genome shared by two individuals because they are inherited from a common ancestor. Regions that are IBD between individuals affected with a disease conceivably can contain the disease gene(s). Two approaches were suggested to clone such IBD sequences.

In GMS (genomic mismatch scanning), each DNA preparation is digested with *Pst*I to yield fragments with protruding 3′ ends. The 3′ protruding ends are protected from digestion by exonuclease III (*Exo*III) in later steps. One of the DNA preparations is fully methylated at all GATC sites with *E. coli Dam* methylase (DAM+). The other DNA preparation remains unmethylated. The two DNA pools are then mixed in equal ratios, denatured, and allowed to reanneal. Digestion of the reannealed DNA with both *Dpn*I and *Mbo*I, which cut at fully methylated and unmethylated GATC sites respectively, results in digestion of the homohybrids. The heterohybrids are resistant to both *Dpn*I and *Mbo*I digestion and survive this treatment. Discrimination between perfect, mismatch-free heterohybrids and those with mismatches is done by the MutHLS enzyme. Only perfect duplexes will escape nicking during this step. All DNA molecules, except mismatch-free ones, are degraded further with *Exo*III. Thus, the full-length, unaltered heterohybrids are purified from the other DNA fragments.

Another method was called *CIS* (cloning of identical sequences). The scheme of the CIS-procedure is shown in Fig. 9.

DNA A and B is digested with *Bam*HI and ligated to special linkers containing two recognition sites for *Mvn*I. DNA A is PCR-amplified in the presence of dUTP and m5dCTP; thus, all cytosines will be methylated. DNA B is PCR-amplified in the presence of normal dCTP and biotinylated primers. The two DNA preparations are mixed in equal ratios, denatured, and hybridized. Subsequently, the DNA is digested with *Mvn*I. This enzyme can digest only dsDNA molecules without methylcytosine and will digest all homohybrids B (they contain at least four sites for *Mvn*I).

The DNA mixture is next treated with mung bean nuclease. This nuclease destroys all imperfect hybrids and ssDNAs. Thus, after this treatment we will have only perfect homohybrids A and perfect (without any mismatches) heterohybrids. The DNA mixture is then treated with UDG (uracil-DNA glycosylase). This enzyme removes the uracil base from the DNA and thus destroys all DNA from individual A. As a result, there will be only ssDNA from individual B, which is identical to the DNA in individual A.

3.5 Strategies to Map and Sequence Genomes; Hierarchical, Whole-genome, and Slalom Sequencing Approaches

During the last few years, impressive progress has been made in mapping and sequencing whole genomes of various organisms. Two basic strategies have so far been employed for genome sequencing.

According to one scheme (hierarchical approach), the whole genome is mapped using different types of markers, and a minimal set of large-insert clones, such

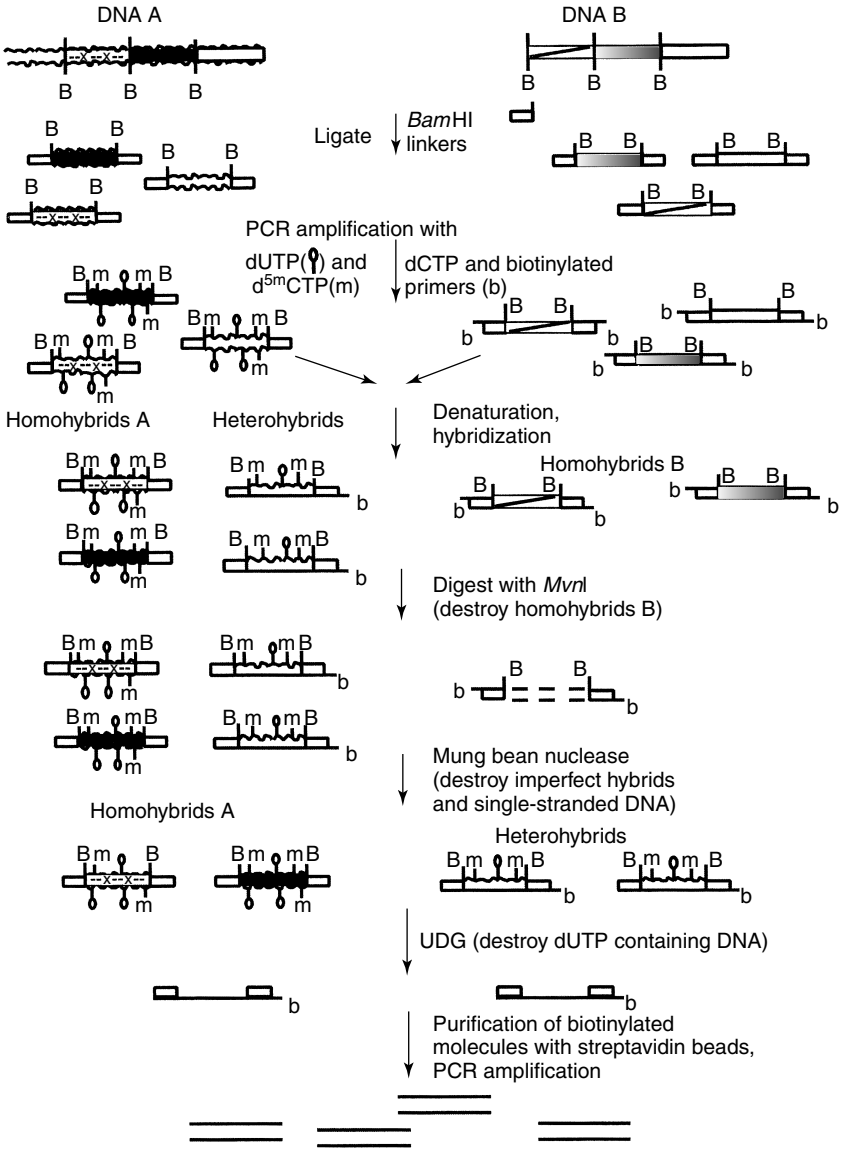

Fig. 9 General scheme of the CIS, cloning of identical sequences, procedure. The same enzymes are used as in the CODE method but in a different order, and the result is opposite.

as cosmids, PAC, or BAC clones, is established. Subsequently, these large-insert clones are sequenced using a shotgun sequencing strategy: small-insert libraries, containing randomly sheared fragments of the large-insert clones, are constructed and sequenced.

A variant of this strategy, the whole-genome shotgun (WGS) sequencing strategy, was developed later and has proved

valuable. This method involves end sequencing of large- (PAC, BAC, cosmids) and small-insert (2 and 10 kb) clones. DNA fragments in the small-insert clones are generated by physical shearing of whole genomic DNA. All resulting reads are joined in one sequence with special computer programs. The WGS method requires the generation of sequences covering the whole genome 10 to 15 times. If sequence coverage is less, then the contig assembly process cannot be completed, and sequences and clones will just represent islands, without connection or order. Therefore, despite impressive technological progress, mapping and sequencing of even small bacterial genomes is expensive and laborious.

After completion of the genomic sequence from one organism, there will be a great demand, in many cases, for comparison with the genomes of other individuals, related species, pathogenic and nonpathogenic strains, and so on, in the growing field of comparative genomics. Such comparisons are highly relevant to our understanding of human and animal health, evolution, and ecology.

An efficient strategy for simultaneous genome mapping and sequencing was recently developed. The approach is based on slalom libraries, which combine features of general genomic, jumping, and linking libraries. First experiments demonstrated the feasibility of the approach, and showed that the efficiency (cost-effectiveness and speed) of existing mapping/sequencing methods can be improved at least 5- to 10-fold. The slalom allows the establishment of a physical map, with minimal sets of overlapping clones, which will pinpoint differences in genome organization between organisms. At the same time, considerable sequence coverage of the genome (about 50%) will be achieved. This will make it possible to locate virtually every gene in a genome, for more detailed (comparative) study. Furthermore, since the efficiency of contig assembly in the slalom approach is virtually independent of sequence read length, even short sequences, as produced by rapid high-throughput sequencing techniques suffice to complete a physical map and sequence scan of a small genome. A combination of these new sequencing techniques with the slalom approach increases the power of the method 10 to 50 times more and makes it an efficient tool for comparative genomics. The main principle of the slalom libraries is shown in Fig. 10.

Two standard genomic *Eco*RI- and *Bam*HI-digested libraries are constructed and they will completely cover the whole genome. The problem is how to put *Eco*RI and *Bam*HI fragments in the correct order. It can be solved using the connecting library. The connecting library can be constructed as follows: DNA isolated ''en masse'' from an *Eco*RI library is digested with *Bam*HI, circularized in the presence of the Kan^r gene, and plated on agar with kanamycin. The clones isolated in this manner will be identical in structure to the clones from an *Eco*RI jumping library prepared in the classical way. By comparing end sequences in these three slalom libraries, all clones can be positioned relative to each other and a minimal contig of overlapping clones may be established.

3.6 Restriction-site-tagged Microarrays to Study CpG-Island Methylation

Methylation, deletions, and amplifications of cancer genes constitute important mechanisms in carcinogenesis, and CGI (CpG-island-containing) microarrays were

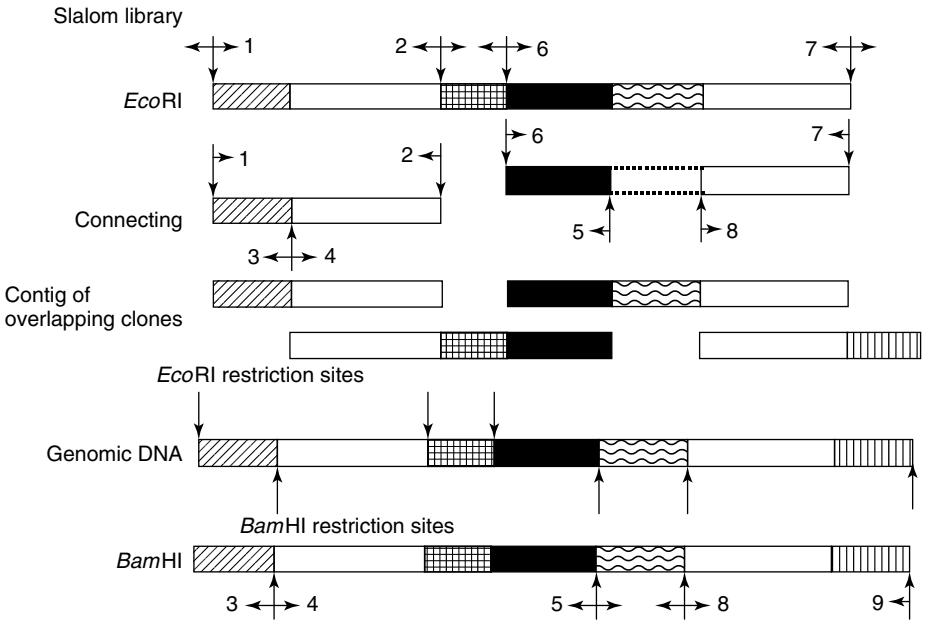

Fig. 10 Simplified slalom library approach scheme. Numbers designate identical end sequences in different libraries that can be joined by a computer program in a contig of overlapping clones. Dashed lines show genomic DNA sequences deleted in the connecting library.

suggested to study hypermethylation in cancer cells. These microarrays can detect methylation changes in tumor DNA. However, it is unclear whether these microarrays can be used to detect hemizygous methylation or copy-number changes. As the whole human genome DNA is used for labeling and the clones are small (0.2–2 kb), this creates a serious problem. Oligonucleotide-based microarrays also can be used to study methylation changes in cancer cells; however, only a limited number of genes can be tested in such experiments.

A rough estimation is that the human genome contains 15 000 to 20 000 *Not*I sites. Therefore, thousands of genes could be tested with *Not*I clone microarrays. The fundamental problems for genome-wide screening using *Not*I clones are (1) the size and complexity of the human genome, (2) the number of repeat sequences, and (3) the comparatively small sizes of the inserts in *Not*I clones (on average 6–8 kb). A special procedure was developed to amplify only regions surrounding *Not*I sites, the so-called *Not*I representations (NRs, see Fig. 8). Other DNA fragments were not amplified. Therefore, only 0.1 to 0.5% of the total DNA is labeled. Interestingly, sequences surrounding *Not*I sites contain 10-fold fewer repetitive sequences than the human genome on average, and therefore, these microarrays are not as sensitive as other methods to the background hybridization caused by repeats. The main idea of this application is clear from Fig. 8 (tumor DNA). If a particular *Not*I site is present in the DNA, then the circle will be opened with *Not*I and labeled. However, if

this *Not*I site is deleted or methylated, then the NR will not contain the corresponding DNA sequences. The *Not*I microarrays can simultaneously detect copy-number changes and methylation and, therefore, they allow the simultaneous study of genetic and epigenetic factors.

The technique underlying the preparation and use of *Not*I microarrays is applicable to any restriction enzyme and represents a new type of microarray, referred to as *restriction-site-tagged* (RST) microarrays. Such RST microarrays can be used for different purposes, for example, to study species composition of complex microbial systems.

3.7 Restriction-site-tagged Sequences to Study Biodiversity

There is still much to learn about the human normal microflora. The human gut contains approximately 1 to 2 kg of bacterial cells. The number of these cells in the intestine is 10 to 100 times larger than the number of cells in the human body, but at best 10 to 15% of the microbial species are known. To be able to analyze complex microbial mixtures is of great importance for many applications. For instance, differences between individual compositions of the normal flora will be instrumental for future analysis of the effects on the normal flora composition of diet, foods, geographical location, and medication. Conversely, the effects of gut microflora on aging, autoimmunity, and colonic cancer risk can be studied.

Analysis of human *Not*I flanking sequences (see Sect. 2.3) have demonstrated that even short sequences surrounding *Not*I sites can yield information sufficient to isolate new genes or uniquely describe eukaryotic or prokaryotic genomes.

These results led to the realization that it would be possible to use short sequences surrounding *Not*I sites or, in general, restriction-site-tagged sequences (RSTS) for the analysis of complex microbial mixtures. The collection of *Not*I tags represents the *Not*I sequence passport or in short *Not*I passport. *Not*I passporting means the process of creating *Not*I tags/passports.

The general design of the experiment is as follows. Genomic DNA is digested with *Not*I and ligated to a linker with *Not*I sticky ends. This linker contains the *Bpm*I recognition sites. This restriction nuclease cuts 16/14 bp outside of the recognition site. The ligation mixture is PCR-amplified with special primers and, finally, 19 bp tags flanking *Not*I sites are generated. DNA from, for instance, fecal samples and surgical specimens is digested with *Not*I, and a *Not*I passport for the particular specimen is generated. A comparison of such passports from different individuals or from the same individual before and after drug treatment will reveal the differences between them.

Analysis of tags for *Not*I, PmeI, and SbfI for 70 completely sequenced bacteria revealed that more than 95% of tags are species-specific and even different strains of the same species can be distinguished. None of these tags matched human or rodent sequences. Therefore, the approach allows analysis of complex microbial mixtures such as those in the human gut and identification with high sensitivity of a particular bacterial strain on a quantitative and qualitative basis.

A similar approach can be used for eukaryotic cells, for example, for analysis of cancer cells.

RSTS-passporting and RST-microarray approaches are mutually complementary. These two approaches are based on completely different biochemical techniques but aim to solve the same problems.

4 Summary

While several different strategies are available to obtain and use DNA markers for identifying and mapping DNA sequences in complex organisms, no single system is likely to suffice for obtaining a complete and accurate map and sequence of the human genome. Rather, a combination of different approaches and vector systems is needed to corroborate data from different sources.

Keywords

Androgenetic Embryo
An embryo with two paternal genomes, and no maternal genome, produced by nuclear transplantation.

Chromatin
DNA packaged around nucleosomes. The degree of packaging differs between active (euchromatic) and inactive (heterochromatic) chromosomal regions.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Edited by Robert A. Meyers.
Copyright © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim.
ISBN: 3-527-30547-5

DNA Methylation
Attachment of methyl (CH_3) groups to the bases of DNA. In mammals, DNA methylation occurs at cytosines that are followed by guanines (at CpG dinucleotides).

Epigenetic Modification
Any heritable, but reversible, alteration of DNA or associated nucleosomes above the level of the DNA sequence. This additional layer of information may indicate the parental origin of the chromosome.

Genomic Imprinting
A parent-of-origin-dependent mechanism whereby certain gene loci become expressed from only the maternal or only the paternal chromosome.

Histone Modification
The histones in nucleosomes can be altered by covalent modifications. At imprinting-control regions, these modifications are different between the parental alleles.

Imprinting and Behavior
Some imprinted domains are associated with behavioral phenotypes, and genetic disruption of certain imprinted genes gives aberrant behavior.

Imprinting and Cancer
The epigenetic maintenance of imprinting is frequently deregulated in cancer. Since imprinted genes are important in cell proliferation and differentiation, such deregulation is probably involved in the process of tumorigenesis.

Imprinting and Growth
Many imprinted genes influence fetal growth and development. Imprinted genes that enhance growth are mostly expressed from the paternal allele. Several other imprinted genes, which reduce growth, are expressed from the maternal allele.

Imprinting-control Regions
DNA sequence elements that are essential for imprinted gene expression. They are modified by DNA methylation and epigenetic modifications on the chromatin.

Nucleosome
The basic structural unit of chromatin, consisting of ~150 bp of DNA wrapped around an octamer of histone proteins (two each of four different histones).

Nutrient Transfer
Imprinted genes are important for the development of the extraembryonic membranes. These are essential for nutrient transfer to the developing embryo.

Parthenogenesis
The derivation of offspring from eggs only. Parthenogenesis is viable in some animal groups, such as in bird species, but is embryonic lethal in mammals because of the functional nonequivalence of the maternal and the paternal genome.

Uniparental Disomy
Inheritance of a particular chromosome in two copies from one parent, with absence of the chromosome from the other parent.

Genomic imprinting is a developmental mechanism in mammals and other organisms leading to repression or expression of genes depending on whether they are inherited from the mother or the father. The imprinted expression of genes is regulated by various epigenetic alterations, including DNA methylation and covalent modifications at histones. A large number of imprinted genes have been identified in placental mammals. Mostly clustered in the genome, these play important roles in embryonic and extraembryonic development, and in behavior. In humans, genetic and epigenetic alterations at imprinted genes are involved in different disease syndromes and in cancer.

1 Genomic Imprinting

Gene expression is not determined solely by the DNA code itself. It depends also on different epigenetic features. The term *epigenetic* is used to refer to mechanisms that do not involve changes in the DNA sequence and that are heritable from one cell generation to the next. Unlike heritable changes due to mutation or directed gene rearrangement (such as in the immunoglobulin genes), epigenetic modifications are reversible and can be removed from genes and chromosomes without leaving behind any permanent change to the genetic material. The main epigenetic modifications by which gene expression can be altered are DNA methylation and modifications to the chromatin. A well-known epigenetic mechanism is X-chromosome inactivation. In mammalian X-chromosome inactivation, sequential epigenetic modifications lead to the (random) transcriptional repression of one of the two X-chromosomes in all the somatic cells of females.

In this article, we consider a particular class of epigenetic imprints, those that mark the parental origin of genomes, chromosomes, and genes. Genes regulated by such ''genomic imprinting'' are expressed depending on whether they are on the maternally or on the paternally derived chromosome. Some imprinted genes are expressed only from the paternal chromosome, whereas others are exclusively expressed from the maternal chromosome. During the last fifteen to twenty years, imprinting has evolved from the initial observations in mouse embryos to a rapidly expanding field with importance

for mammalian development and genetics, and human disease. A large number of imprinted genes have now been identified. In addition, molecular studies have unraveled the underlying molecular mechanisms. Imprinting is not unique to mammals but is known to occur in seed plants and invertebrate species as well. This article, however, focuses on the regulation and role of autosomal imprinted genes in mammals.

Following the discovery of genomic imprinting, and the identification of the first imprinted genes in mammals, researchers in the field hypothesized that the epigenetic marks that regulate parent-of-origin-dependent expression are established in either the female or the male germ line and (after fertilization) are maintained throughout development. This epigenetic information needs to be removed upon passage of the imprinted gene through the germ line in the developing fetus, however, so that new imprints can be established. Recent studies on DNA methylation and other epigenetic modifications showed that, indeed, there are three distinct phases in imprinting: establishment of the imprint in the male or female germ line, somatic maintenance of the imprint after fertilization, and its erasure upon (re-)passage through the germ line (Fig. 1).

1.1 Embryological Evidence

Embryological studies in the mouse provided the first evidence that, in mammals, both a maternal and a paternal genome are required for the production of viable offspring. Significantly, it was found that monoparental embryos, carrying either two maternal or two paternal genomes, cannot develop to term. Such monoparental embryos were obtained by nuclear transplantation, immediately following the fertilization of the egg by the sperm. By replacing the female pronucleus (female genome) with a male pronucleus (male genome), for example, it was possible to produce androgenetic embryos (which have two paternal genomes). Conversely, embryos with two maternal genomes (gynogenotes) were made by replacing the male pronucleus with a female pronucleus. Embryos with two maternal genomes were derived by activation of unfertilized eggs (parthenogenesis) as well. Intriguingly, both gynogenetic (parthenogenetic) and androgenetic embryos survived only for a few days after implantation in the uterus and were found to have major developmental abnormalities.

Gynogenetic (parthenogenetic) and androgenetic embryos have different developmental phenotypes (Fig. 2). After

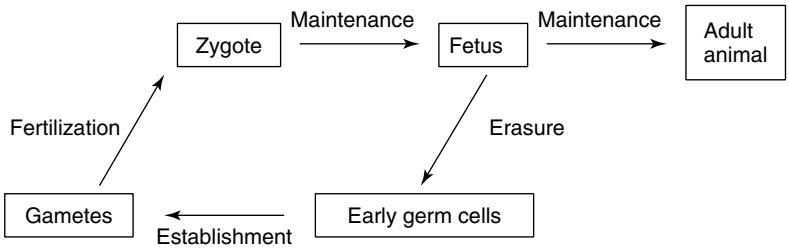

Fig. 1 Ontogeny of genomic imprinting: germ line establishment, somatic maintenance, and erasure.

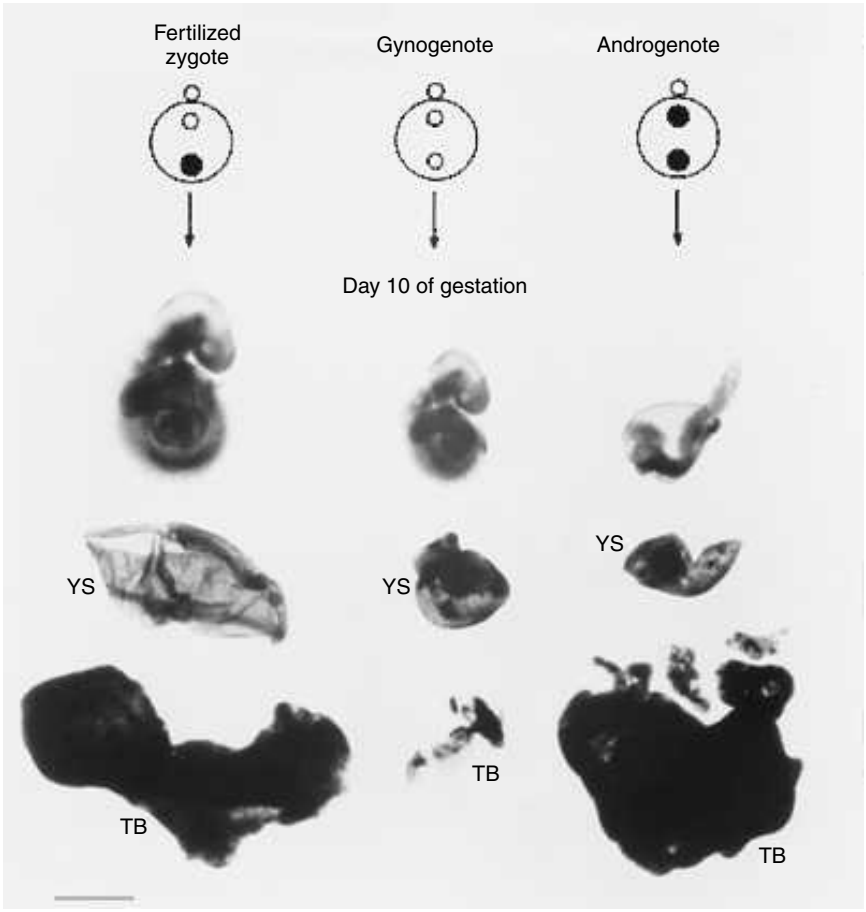

Fig. 2 Normal, androgenetic, and gynogenetic mouse embryos and their extraembryonic membranes at day 10 of gestation. Shown are the embryo, the yolk sac (YS), and the trophoblast (TB).

implantation into recipient females, parthenogenetic conceptuses develop to only about day 10 of gestation, with an apparently normal but small embryo. Development of the extraembryonic membranes (yolk sac and trophoblast), in contrast, is severely deficient, and these are the tissues that are important for nutrient transfer to the embryo. The phenotype of androgenetic conceptuses is opposite to that of parthenogenetic conceptuses. Whereas the extraembryonic tissues are normal in the androgenetic conceptuses, the embryo proper is retarded and progresses rarely beyond the four- to six-somite stage. The investigations on monoparental embryos established that both the parental genomes are required for normal mammalian development. They also provided evidence for the existence of genetic loci at which expression depends on the parental origin of the gene. In parthenogenetic and androgenetic embryos, individual imprinted genes are either expressed from both the

gene copies (double gene dose) or are not expressed at all. Cumulatively, the aberrant levels of expression of imprinted genes are responsible for the striking phenotypes of the two types of monoparental embryos.

1.2 Imprinted Chromosomal Domains

The embryological evidence from the monoparental embryos was reinforced by genetic studies demonstrating that specific chromosomal domains are subject to imprinting. Particularly, mice that were heterozygous for chromosomal translocations were intercrossed to obtain embryos and offspring with uniparental disomy for individual chromosomes (or chromosomal regions). Since during meiosis there is sometimes nondisjunction at the chromosome with the translocation, some of the resulting gametes comprise two copies of the translocated chromosome, whereas others contain none. Embryos that arise from two of such opposite gametes will have two copies of all the chromosomes, but for the translocated chromosome, both the copies will be paternal or maternal. By using different translocation lines, such uniparental disomic embryos were generated for almost all autosomal chromosomes. Phenotypic analyses unraveled the role of subsets of imprinted genes that reside in two paternal or two maternal copies in the different uniparental disomies. These studies also revealed that the maternal and paternal copies of individual chromosomal regions have frequently opposite roles in development and after birth (Fig. 3).

One of the imprinted domains is on the distal portion of mouse chromosome 7. When present in two maternal copies (maternal disomy), it leads to reduced growth and fetal death, whereas paternal disomy of this distal region is associated with enhanced growth and embryonic death. Some 10 imprinted genes have been mapped to this region. Several of these are part of the insulin-like growth factor/insulin signaling pathway (IGF/INS pathway). Being key players in the regulation of fetal growth and development, they contribute to the opposite growth phenotypes in the maternal and paternal distal-7 disomies. The corresponding chromosomal region in humans, chromosome 11p15.5, is involved in the Beckwith–Wiedemann syndrome (BWS), a human growth disorder that can be caused by paternal disomy of this imprinted region.

Another chromosomal domain with opposite phenotypes in paternal and maternal disomies is the proximal portion of chromosome 11. Mice with paternal disomy of this region are larger than their normal littermates, whereas maternal disomy mice are smaller. This indicates that there are imprinted genes in this region, of which aberrant levels of expression in the maternal and paternal disomies cause their abnormal growth. So far, two imprinted genes have been identified in this domain, *U2af1-rs1* and *Grb10*. The latter could be responsible for the phenotypes of the maternal and paternal disomies. Its main embryonic transcript is expressed from the maternal allele only, and it encodes a protein with a negative effect on the growth-regulating IGF/INS pathway.

Disomy phenotypes at a few other imprinted domains involve abnormal postnatal behavior. Paternal disomy for distal mouse chromosome 2, for instance, gives offspring that are hyperactive, whereas maternal disomy is associated with reduced activity after birth. Such behavioral phenotypes emphasize that imprinted genes can affect behavior. A small number of

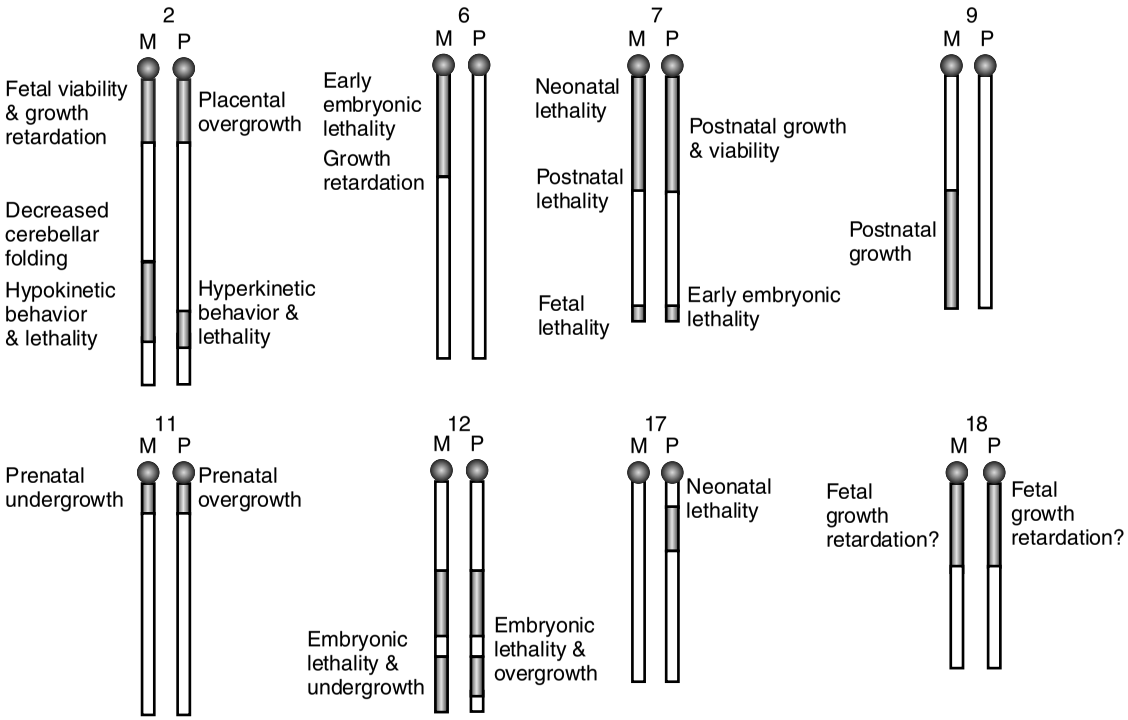

Fig. 3 Imprinted chromosomal domains in the mouse with the associated developmental phenotypes in maternal (indicated to the left) and paternal (to the right) disomies.

imprinted genes were discovered on distal mouse chromosome 2. Two of these have neuroendocrine functions (*Gnas* and *Gnas-xl*) and are involved in the behavioral phenotypes of the maternal and paternal disomy mice.

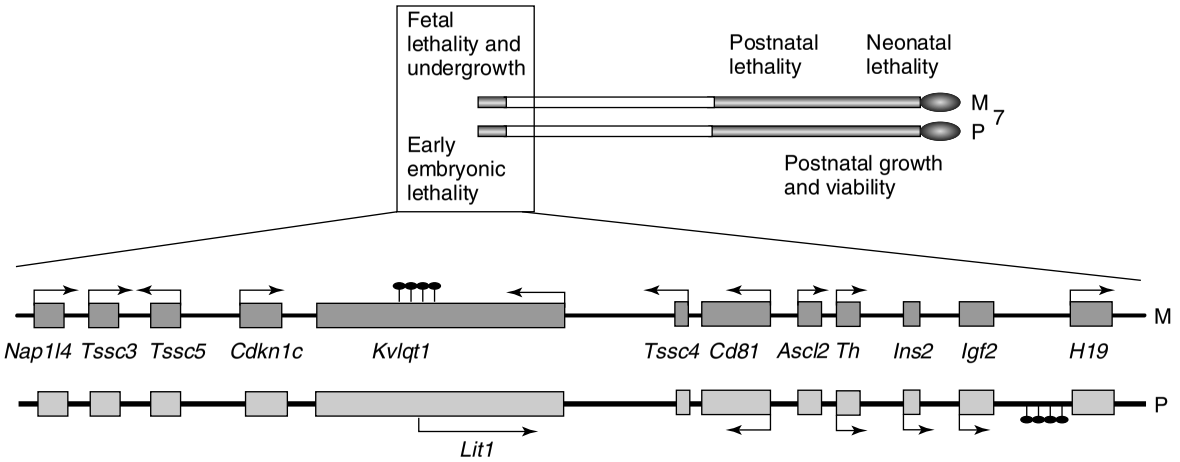
In total, 12 chromosomal regions with imprinting phenotypes have been identified on 8 different autosomal chromosomes (Fig. 3). The large majority of the known imprinted genes maps to these chromosomal regions. Probably, the remainder of the genome comprises few imprinted genes or contains imprinted genes that give rise to minor phenotypes only when present in two maternal or two paternal copies.

2 Imprinted Genes

It is unknown which proportion of mammalian genes is imprinted and estimates vary between about 100 and a 1000 genes. To date, however, some 70 imprinted genes have been detected in the mouse and most of these are imprinted in humans as well. A consistent feature of imprinted genes is that they are organized in clusters in the genome. These clusters are hundreds to several thousands of kilobases in size and are similarly organized in humans and mice. We selected several imprinted clusters as examples, and we describe their roles in development and behavior. A comprehensive presentation of imprinted genes is given elsewhere.

A well-known imprinted cluster is on distal mouse chromosome 7 (Fig. 4) and on the corresponding chromosome 11p15.5 in humans. This cluster comprises 11 imprinted genes. Several of these genes play key roles in fetal growth and development. The insulin-like growth factor-2 gene (*Igf2*), at the proximal side of the cluster, is expressed from the paternal allele only. Transgenic mice inheriting a null *Igf2* allele from the father are much smaller than their littermates; maternal inheritance of the targeted allele does not alter the phenotype. This strong paternal effect on fetal growth is primarily due to the loss of IGF2 in the extraembryonic membranes, which decreases nutrient transfer to the developing fetus. The neighboring insulin-2 gene (*Ins2*), also of the IGF/INS pathway, is located at about 20 kb from *Igf2*. In the yolk sac, it is the paternal chromosome that expresses *Ins2*, whereas the maternal chromosome is repressed. The paternal expression of *Igf2* and *Ins2* is regulated by an ''imprinting-control region'' downstream of *Igf2*, close to a maternally expressed imprinted gene (*H19*) that produces a noncoding RNA. At the distal side of the cluster, the *Cdkn1c* gene (also called *p57Kip2*) codes for a cyclin-dependent kinase inhibitor. This imprinted gene is expressed from the maternal allele only. When *Cdkn1c* expression is ablated by gene targeting in the mouse, offspring are enhanced in size and also display other similarities to the Beckwith–Wiedemann syndrome in humans. Interestingly, a similar growth phenotype arises as a consequence of *Igf2* overexpression in mice. One role of CDKN1C could therefore be to inhibit the growth-promoting action of IGF2. Thus, several genes in the imprinted gene cluster are involved in the regulation of fetal growth and seem part of the same signaling pathway.

Four of the other imprinted genes at the distal 7 cluster display allelic expression in the extraembryonic tissues, in which they are expressed from the maternal allele. One of these, *Ascl2* (also named *Mash2*) encodes a transcription factor that is essential for placental development. Genetic studies



Gene	Product	Function
Tssc3	Pleckstrin homology-domain protein	Placental development
Cdkn1c	Cyclin-dependent kinase inhibitor	Tumor suppressor gene
Kvlqt1	Voltage-dependent potassium channel	Heart and ear function
Lit1	Noncoding RNA	Imprinting regulator?
Ascl2	Transcription factor	Placental development
Ins2	Growth factor	Embryonic growth
Igf2	Growth factor	Embryonic growth
H19	Noncoding RNA	Translational control?

Fig. 4 The imprinted domain on distal mouse chromosome 7 (human chromosome 11q15). Shown are the imprinted genes and their known functions. Lollypops indicate the allele-specific DNA methylation at the two imprinting-control regions.

show that the imprinting of the four extraembryonic genes, and that of *Cdkn1c*, is regulated by a second ''imprinting-control region,'' which is located in the central portion of the cluster.

Amongst the imprinted genes that influence the IGF/INS pathway, there is also the IGF2-receptor gene (*Igf2r*) on mouse chromosome 17. *Igf2r* is expressed exclusively from the maternal allele and exerts a negative effect on growth by reducing the levels of active IGF2. Whereas most imprinted mouse genes are imprinted in humans as well, *Igf2r* is one of the exceptions. In humans, this gene is expressed from both the parental alleles.

Some chromosomal domains comprise imprinted genes that are expressed predominantly in the brain. One of these clusters maps to the central portion of mouse chromosome 7 (and to human chromosome 15q11–q13) and comprises a large number of genes that are all expressed from the paternal chromosome only (Fig. 5c). In humans, loss of expression at these genes (*SNRPN, ZNF127, NDN*, and others) leads to the Prader–Willi syndrome, a variable disorder that is partly due to a hypothalamic defect (see below). Biallelic expression of the genes and loss of expression of a neighboring imprinted gene (*UBE3A*) is associated with the clinically distinct Angelman syndrome (AS). The regulation of imprinting in this domain is complex and involves at least two distinct genetic elements.

A minority of imprinted genes are not part of an imprinted gene cluster. One of these is the U2af1-related sequence-1 gene (*U2af1-rs1*) on proximal mouse chromosome 11. This intronless gene is repressed on the maternal chromosome and encodes a brain-specific RNA splicing factor homologous to the splicing factor U2AF. The imprinted *U2af1-rs1* gene has arisen via a retrotransposition event in rodents, and in humans there is no equivalent imprinted gene.

3 Molecular Mechanisms

3.1 Imprinting-control Regions

The expression of imprinted genes is regulated by epigenetic modifications that mark the parental alleles to be active or repressed. These epigenetic modifications are put onto key regulatory elements, depending on the parental origin of the allele, and lead to the allelic gene expression.

At all imprinted loci, there are sequence elements at which DNA methylation is present on one of the two parental alleles only. At many of these ''differentially methylated regions'' (DMRs), the DNA methylation originates from either the egg or the sperm. After fertilization, the allelic methylation is maintained in the somatic cells. Regions with such a germ line methylation mark are essential in the control of imprinting. They are referred to as *imprinting-control regions*. Most imprinting-control regions are rich in CpG dinucleotides and correspond to CpG islands.

At the imprinted *U2af1-rs1* gene, DNA methylation is present exclusively on the repressed maternal allele (Fig. 5a). This differential DNA methylation becomes established during oogenesis along its CpG island, located at the 5′ side of the gene, and spreads throughout the entire maternal gene during early embryonic development.

The maternally expressed *Igf2r* gene has an imprinting-control region within the second intron that is methylated on the

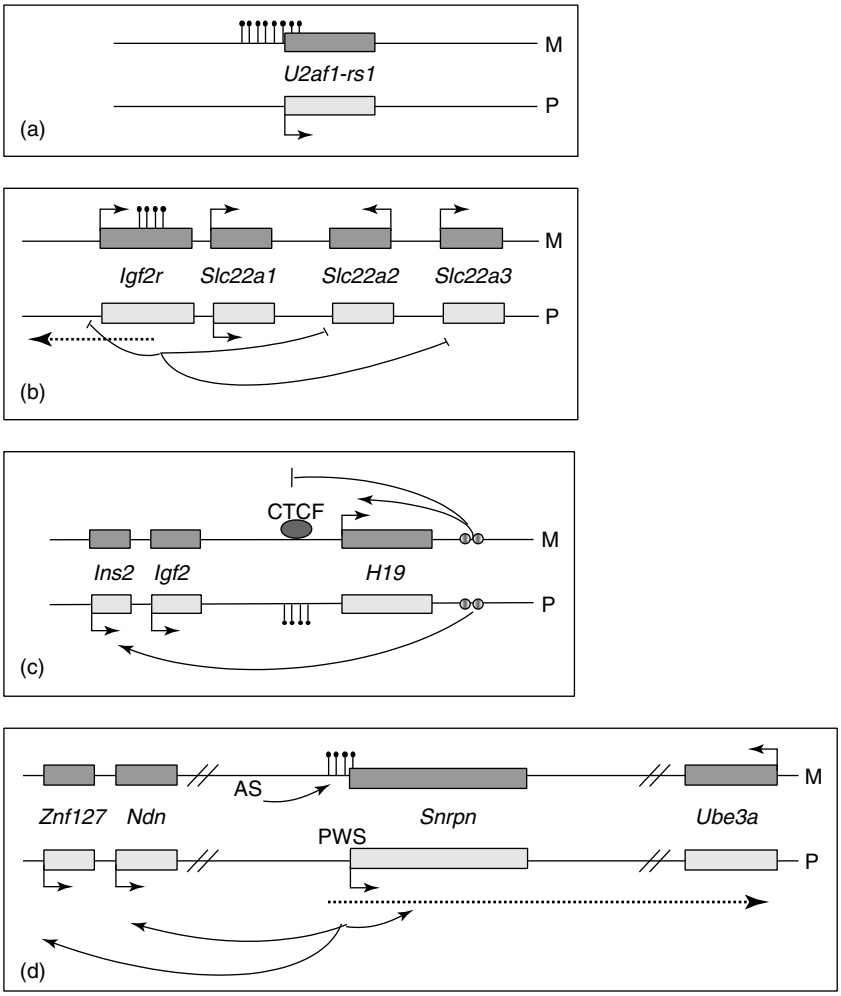


Fig. 5 Reading the imprint. Imprinting-control regions confer allelic gene expression at the (a) *U2af1-rs1* gene, (b) the Igf2r locus, (c) the imprinted cluster containing the *Igf2* gene, and (d) at the PWS/AS region in the mouse. Lollypops indicate the allele-specific DNA methylation at the imprinting-control regions. Antisense transcripts are shown as interrupted lines; circles indicate transcriptional enhancers.

maternal allele (Fig. 5b). This maternal methylation is established during oogenesis and is maintained in all the somatic lineages. The intronic imprinting-control region is essential for the allelic repression at the locus: removal by gene targeting leads to expression from both the parental alleles.

Most imprinting-control regions are methylated on the maternal allele. However, in some, the DNA methylation is found at the paternal allele, and it is the maternal allele that is unmethylated. One of these paternal methylation marks controls the allelic expression of the *Igf2* and *Ins2* genes on distal mouse chromosome 7

(Fig. 5c). This region, a CpG island located upstream of the close-by *H19* gene, acquires its DNA methylation during spermatogenesis. After fertilization, this paternal mark is maintained in all the somatic tissues. Deletion of the control region gives rise to biallelic expression of *Igf2* and *Ins2*.

It is unclear why imprinting-control regions attract DNA methylation in either the female or the male germ line. Several studies suggest, however, that close-by tandemly-repeated sequences might be essential in this choice process.

More is known about the DNA methyltransferases (DNMT) that are involved in the germ line establishment of the methylation marks. The methyltransferases DNMT3A and DNMT3B are essential in this process. In addition, a DNMT-like protein (DNMT3L) is required for the establishment of methylation imprints as well, particularly in the female germ line. Once established, allelic patterns of DNA methylation need to be maintained in the developing embryo. The maintenance methyltransferase, DNMT1, plays an important role in this process and differential chromatin features are likely to be involved as well. At imprinting-control regions, pronounced differences in histone modifications have been detected between the parental alleles. Levels of histone acetylation are low on the allele that comprises methylated DNA, whereas high levels of acetylation are present on the chromatin of the opposite, unmethylated, allele. In addition, there are strong allelic differences in histone methylation at specific lysine residues on histone H3. Whereas methylation of lysine residue 9 of H3 is detected on the parental allele that has DNA methylation, it is on the opposite parental allele (without DNA methylation) that there are high levels of H3 lysine-4 methylation. At several imprinted loci, there is also evidence for allele-specific chromatin compaction, occurring in association with the differential histone modifications.

It is not yet understood how DNA methylation, histone acetylation, and histone methylation are mechanistically linked at imprinting-control regions. However, at several imprinting-control regions, (allelic) DNA methylation was found to be linked to histone deacetylation (the removal of the acetyl group from the histones). This link is brought about by proteins that bind the methylated DNA and attract large protein complexes that comprise histone deacetylases. It is to be explored also to which extent the differential histone modifications are important in the somatic maintenance (and germ line establishment) of the allelic patterns of DNA methylation at imprinted loci. Nonhistone proteins, binding to the unmethylated allele of many imprinting-control regions, are likely to be involved in the maintenance of the allelic DNA methylation as well.

3.2 Reading the Imprint

Imprinting-control regions are comparable in that they all have allele-specific DNA methylation and differential chromatin organization. The way in which this gives rise to imprinted gene expression differs between loci. The simplest scenario, whereby differential methylation and associated chromatin features lead to imprinted gene expression, is that of the *U2af1-rs1* gene on mouse chromosome 11 (Fig. 5a). Here, methylated DNA and compacted chromatin are present across the promoter on the maternal allele. As a consequence, the gene can be transcribed from the paternal allele only.

The imprinting-control region of *Igf2r* regulates allelic expression in a rather different way (Fig. 5b). Here, the maternal methylation covers the promoter of an antisense transcript. As a consequence, this antisense transcript (named *Air*) is produced from the (unmethylated) paternal allele only. Via a yet-unclear mechanism, this paternal antisense transcript represses the paternal *Igf2r* gene and two flanking ion-transporter genes (*Slc22a2* and *Slc22a3*). A similar antisense transcript is produced at the imprinting-control region that regulates the extraembryonic tissue-specific imprinted genes on distal mouse chromosome 7 (Fig. 3).

Another example of how a germ line mark conveys imprinted expression is provided by the *Ins2-Igf2-H19* locus on distal mouse chromosome 7 (Fig. 5c). Here, the imprinting-control region located upstream of the noncoding *H19* gene, is methylated on the paternal allele and acts as a chromatin boundary on the unmethylated maternal allele. In fact, this upstream element has multiple recognition sites for a zinc finger protein called CTCF. The binding of CTCF is prevented by methylation. This chromatin protein is therefore associated with the unmethylated maternal allele only, at which it forms a specialized chromatin structure. This unusual structure insulates the *Igf2* and *Ins2* promoters from their enhancers (located downstream of *H19*). As a consequence, *Igf2* and *Ins2* are repressed on the maternal chromosome. This maternal repression is not exclusively at the transcriptional level but influences posttranscriptional processes as well.

The central portion of mouse chromosome 7 (Fig. 5d) corresponds to the Prader–Willi syndrome (PWS) region and Angelman syndrome (AS) region on human chromosome 15q11–13. The key regulatory element in this domain is the 5′ portion of the *SNRPN* gene and it is methylated on the maternal chromosome. This imprinting-control region is essential for the paternal expression of *SNRPN* and its flanking genes (including *Znf127* and *Ndn*). When the element is deleted on the paternal chromosome, these brain-specific genes are all no longer expressed. Upstream of the *SNRPN* gene, a paternal RNA of several hundreds of kilobases in size is produced as well. This transcript is in antisense orientation to a gene at the far extremity of the imprinted domain. This gene, *UBE3A*, is the only one in the cluster that is repressed on the paternal chromosome. The *SNRPN* imprinting-control region itself is regulated by a second control region, which is located further upstream, and is essential for the acquisition of the allelic DNA methylation at *SNRPN*. Precisely how the allelic expression and repression is brought about along thousands of kilobases remains to be unraveled. It has been observed, however, that there is differential timing of replication in the S-phase between the parental chromosomes along the entire domain. Such a differential replication timing has been detected at other imprinted loci as well. Future work should investigate the role of the differential replication timing and whether it reflects differential chromatin organization along entire imprinted domains.

4 Imprinting and Disease

In many genetic diseases, the clinical manifestations depend on whether the mutation is inherited from the mother or the father. Although imprinting is suspected to be involved, causal genes and molecular mechanisms are yet to

be identified for most of these disorders. Clinical phenotypes can be associated with uniparental disomies as well, similarly as in the mouse. Additionally, imprinting can become deregulated during embryonic development, by epigenetic alterations or by somatic mutations, resulting in loss or biallelic expression of imprinted genes. Such somatic loss of imprinting can result in specific disease phenotypes as well.

Beckwith–Wiedemann syndrome (BWS) is a fetal overgrowth syndrome with a high incidence of embryonal tumors, including Wilms' tumor of the kidney and rhabdomyosarcoma. Genetically, the syndrome is linked to the cluster of growth-related imprinted genes comprising *IGF2* (see Fig. 4). Paternal disomy of this domain is responsible for a proportion of cases and leads to a double dose of *IGF2* expression and loss of expression of *CDKN1C* and other maternally expressed genes in the cluster. BWS can also be caused by genetic mutations at *CDKN1C* and by alterations at the *KVLQT1* gene, where there is one of the two imprinting-control centers of the cluster. The finding that the growth syndrome can be caused by mutations at different places in the imprinted domain supports the idea that its genes are coregulated and involved in the same biological functions. The majority of the BWS cases are sporadic, however, and apparently without genetic mutations. These are mostly caused by epigenetic alterations in the developing embryo. In some of the sporadic cases, for instance, there is aberrant, biallelic methylation at the imprinting-control region at the *H19* gene (Fig. 5c). This results in expression of *IGF2* from both the parental chromosomes during development and therefore in fetal overgrowth.

The neurobehavioral Angelman syndrome (AS) includes mental retardation, ataxia, and hyperactivity and arises from maternal deletion or paternal disomy of the imprinted domain on chromosome 15q11–13. Prader–Willi syndrome (PWS), on the other hand, arises from paternal deletion or maternal disomy of this imprinted domain. This opposite syndrome involves mild mental retardation, obesity due to hyperphagia, and hypogonadism. Cases with small genetic deletions have been identified, and analysis of these patients has revealed that the PWS and AS are caused by distinct regions in the large imprinted domain (Fig. 5d). The smallest identified deletions in PWS remove the imprinting element at the 5′ portion of *SNRPN*. This gives loss of expression of *SNRPN, NDN, ZNF127*, and several other genes in the cluster. The smallest deletions in AS removes the control region that is essential for the establishment of the epigenetic imprint at *SNRPN*. Consequently, there is expression of *SNRPN, NDN*, and *ZNF127* from both the parental alleles and loss of expression of the *UBE3A* gene located at the end of the cluster. The latter seems to be the main cause of the clinical phenotype of AS.

Amongst other imprinting disorders are Albright Hereditary Osteodystrophy (AHO), linked to a cluster of imprinted neuroendocrinal genes on human chromosome 20q, and transient neonatal diabetes mellitus (TNDM), linked to chromosome 6q24–25. The latter is mostly sporadic and is caused by aberrant expression of the imprinted gene *ZAC*. This zinc finger protein–encoding gene has a CpG island with maternal DNA methylation. It was discovered recently that in cases of TNDM without genetic defects, this imprinting-control region has lost its methylation.

Epigenetic alterations at imprinting-control regions occur frequently in tumors

as well. This has been observed in Wilms' tumor of the kidney, but also in lung cancer, breast cancer, and various other cancers. In particular, *IGF2* was found to be expressed from both the parental alleles during tumorigenesis and this could confer a proliferative advantage to the cells. In many cases, the biallelic *IGF2* expression is caused by acquisition of DNA methylation at the imprinting-control region upstream of *H19*, similarly as in BWS. This epigenetic alteration occurs early in tumor formation and could be linked to the pathological tendency of tumorigenic cells to acquire methylation at CpG islands.

When early embryos are taken from their natural environment and put into a culture dish, it can lead to aberrant imprinting as well. This was observed in the mouse and in domestic animals. It is unclear, at present, whether loss of imprinting due to embryo culture is mechanistically comparable to that in human imprinting disorders or in tumors. However, culture of embryos and early embryonic cells can also induce aberrant DNA methylation at imprinting-control regions. This results in biallelic, or loss of, imprinted gene expression and can have pronounced phenotypic consequences at later developmental stages. An important issue to be investigated is whether there are culture conditions that do not affect imprinting and would thus be best suitable for *in vitro* culture and manipulation procedures in animals and humans.

5 Evolution of Imprinting

There is a lot of interest in how broadly imprinting is conserved amongst mammals. Also, in species other than the mouse, both the parental genomes are essential for normal development. Parthenogenesis, for instance, leads to embryonic lethality in humans, pigs, and sheep. In the latter (ruminant) species, parthenogenetic conceptuses die shortly after implantation, due to deficient development and functioning of the extraembryonic membranes. These studies indicate that imprinting is conserved amongst different groups of mammals. Indeed, most of the known imprinted mouse genes are also imprinted in humans and, as far as this has been analyzed, in other placental mammals as well.

Evolutionary biologists have proposed several hypotheses to explain why imprinting has arisen in placental mammals and to account for the different imprinting-related phenotypes. In placental mammals, there is continuous transfer of nutrients from the mother animal to the developing offspring, and this determines their development and growth. Possibly, the most attractive theory of imprinting says that paternally inherited genes tend to increase nutrient transfer and thereby the growth of the developing fetus. This would enhance their chances of being propagated to future generations. Maternally derived genes, however, would be best propagated by limiting the growth of the developing fetus. This is because too high a burden of nutrient transfer compromises the reproductive success of the mother animal and hence of all its offspring. During the evolution of placental mammals, there would therefore have been a 'parental tug-of-war' between these opposing maternal and paternal strategies, leading to balanced combinations of expression levels of maternally and paternally derived genes. As outlined with different examples, imprinted genes such as *Igf2, Ins2*, and *Igf2r* indeed play important roles in nutrient

transfer and growth, for instance, by promoting or reducing the development of the extraembryonic tissues. Other imprinted genes are important in determining the activity of the newborn animals, which, again, could have an impact on nutrient transfer, but now after birth.

Keywords

Oxidative Stress
Excess accumulation of reactive oxygen species (ROS) resulting from metabolism, exposure to environmental oxidants, toxicants, radiation, or numerous biotic and abiotic stresses, which perturb cellular redox balance to a more oxidized state and disrupt normal biological functions, often leading to cell death.

Reactive Oxygen Species (ROS; Including "Free Radicals")
Highly reactive oxygen intermediates, which, at certain cellular concentrations are highly toxic to cells often leading to cell death. These include hydrogen peroxide, superoxide anion, hydroxyl radicals, and singlet oxygen. At cellular equilibrium, ROS may play key signaling roles in gene expression.

Signal Transduction
A mechanism by which cells or organisms perceive a signal and transmit it via the proper pathways to elicit a genomic response.

Genome
The totality of a cell's genetic information, including genes and other DNA sequences.

Gene
A segment of the genome (DNA) that codes for a functional product.

Promoter
A sequence of nucleotides on the DNA that is required for the initiation of transcription by RNA polymerase.

Genomic Fluidity
The capacity of the genome to reorganize rapidly in response to a given stimulus or signal.

The environment in which they exist affects all living organisms. Differences among individual organisms in response to environmental stresses are common, whether the stress factors are natural environmental variations, infectious agents, environmental chemicals, or any other natural or anthropogenic environmental variables. During their evolution, organisms have evolved a variety of ways of adapting to environmental changes. However, the underlying mechanisms by which cells or organisms perceive environmental adversity and mobilize their defenses to it are just beginning to be understood. Such an understanding is essential in any future attempts to engineer organisms for greater tolerance or resistance to more frequent and rapid environmental changes. As a consequence of recent developments in molecular biosciences and elucidation of the human and other genomes and genomic analyses, a deeper appreciation of the mechanisms by which genes may perceive environmental signals and start a cascade of biochemical events to effect a response to a given signal is now emerging. The most fundamental stress encountered by all aerobic organisms is ''oxidative stress,'' which is a consequence of the aerobic lifestyle on our planet. A broad range of environmental stresses affecting prokaryotes and eukaryotes are directly or indirectly related to oxygen toxicity. Organisms have evolved sophisticated ways of coping with life in an oxygen-requiring environment. This oxygen paradox is dealt with below.

1 Introduction

Every living organism is affected by its environment. The environment, whether internal or external to the organism, is continually changing, and the organism must adapt if it is to survive. However, an organism apparently well adapted to the environment at any one time may be poorly adapted only a short time later if it cannot modify its physiology or behavior in response to changing conditions. Organisms that can adjust to changes in the environment are likely to exhibit a greater degree of adaptiveness than those that cannot. Environmental changes, irrespective of its source, cause a variety of ''stresses'' or ''shocks'' that a cell must face repeatedly, and to which its genome must respond in a programmed manner for the organism to survive. Thus, a dominant theme in modern biology is gene expression. It is desirable to determine how genes are expressed in a selective manner in response to an external or internal signal or stimulus. Examples are responses to light, oxidative stress, pathogenicity, wounding, anaerobiosis, thermal shock, and the ''SOS'' response in microorganisms. For cells of any organism to respond to external cues, they must be able to perceive these cues or signals and transduce such perceptions into the appropriate response. Some sensing mechanism(s) must be present to alert the cell to imminent danger and to trigger the orderly sequence of events that will mitigate this danger. In addition, there are genomic responses to unanticipated, unprogrammed challenges for which the genome is unprepared, but to which it responds in discernible though initially unforeseen and unpredictable ways. Many, though not all, signals are perceived at

the cell surface by plasma membrane receptors. Activation of such receptors by mechanisms such as ligand binding may lead to alterations in other cellular components, ultimately resulting in alterations in cell shape, ion conductivity, gene activity, and other cellular functions. Identification and isolation of mutants that are unable to respond, or that respond abnormally to a particular signal may provide ways to decipher the mechanisms by which a particular signal is transduced into a given response. Long before humans began manipulating and altering their environment, organisms from the simplest to the most complex began evolving methods to cope with stressful stimuli. Consequently, most living cells possess an amazing capacity to cope with a wide diversity of environmental challenges, including natural and synthetic toxins, pathogens, extreme temperatures, high metal levels, and radiation. Many studies in the past have demonstrated clear ''cause-and-effect'' relationships upon exposure of a given organism or cell to a particular environmental factor or stressor. However, only recently have certain environmental insults been shown to elicit specific genomic responses. At present, little is known of the underlying molecular mechanisms by which the genome perceives environmental signals and mobilizes the organism to respond. Such information is not only interesting in and of itself, but is also essential in any future attempts to engineer organisms for increased tolerance to environmental adversity. Recent dramatic advances in molecular biology and genomics have made it possible to investigate the underlying mechanisms utilized by organisms to cope with environmental stresses. Investigations of genomic responses to challenge are shedding light on unique DNA sequences capable of perceiving stress signals, thus allowing the cell or organism to mobilize its defenses. The general picture emerging from recent studies involves the sensing of a signal and the transduction of the signal to the transcription apparatus to catalyze transcription initiation. The steps involved in such a process may be summarized as follows:

- A signal, normally the intracellular or extracellular concentration of a small molecule, is perceived by a sensor.
- The signal is then transmitted to the regulatory ''activator'' protein.
- The signal transduction changes the conformation of the activator protein.
- The altered activator protein binds to a specific DNA site.
- The DNA–protein interaction catalyzes the binding or activity of RNA polymerase to facilitate transcription initiation.

2 Gene Responses

Terminally differentiated cells express an array of genes required for their stable functioning and precise metabolic roles. A genome can respond in a rapid and specific manner by selectively decreasing or increasing the expression of specific genes. Genes whose expression is increased during times of stress presumably are critical to the organism's survival under adverse conditions. Examination and study of such ''stress-responsive'' genes has implications for human health and well being, for agricultural productivity, and for furthering basic biological knowledge. In addition to aiding the organism under stress, genomes that are modified by

stress can be utilized to study the molecular events that occur during periods of increased or decreased gene expression. The mechanisms by which an organism recognizes a signal to alter gene expression and responds to fill that need are important physiologically and render possible the examination of gene regulation under various environmental regimens. The mechanisms of induction of stress response in genes are similar among various organisms examined. Similarities in stress-induced changes in gene expression have been observed for a variety of stressors. Some that have been studied in detail include radiation, thermal shock, pathogenic infections, anaerobiosis, trauma, photostress, physical wounding, oxidative stress, water stress, and heavy metals. In all cases, specific changes in transcript and/or protein expression have been observed in various organisms subjected to such challenges.

Recently, numerous studies by several laboratories using a variety of organisms indicate that oxidative stress is a common denominator underlying many diseases and environmental insults, which can lead to cell death in virtually all aerobes. It is also becoming clear that a variety of different biotic and abiotic stresses cause their deleterious effects, directly or indirectly, via reactive oxygen species (ROS) generation.

For example, numerous toxic environmental chemicals such as xenobiotics, pesticides, herbicides, fungicides, ozone, cigarette smoke, and radiation, cause harmful environmental effects via generation of free radicals and other reactive oxygen species.

The focus of this report will be on oxidative stress, its causes and consequences, and mechanisms employed by organisms to cope with it.

3 Oxygen and Oxygenation of the Earth

Of all the planets in our solar system, only Earth is known to contain molecular oxygen (O_2) in its atmosphere and to support aerobic life. However, when Earth was formed about 4.5 billion years ago, its atmosphere was unlike the present, being primarily reducing and essentially free of oxygen. The earliest living organisms were most likely anaerobic heterotrophs living in the primitive ocean depths, shielded from the damaging effects of solar ionizing radiation. The earliest relatively low levels of oxygen were likely the result of photolytic dissociation of water by the sun's ionizing radiation. The bulk of Earth's present oxygen concentration (21% O_2) is derived from the photosynthetic activities of cyanobacteria and plants. It has been estimated that the earth contains about 410×10^3 Emol (1 Erda mole $= 10^8$ mol) of oxygen, and of this, 38.4×10^3 Emol is in the hydrosphere as water. Molecular oxygen is present in the atmosphere (37 Emol) and in the hydrosphere (0.4 Emol) and undergoes continuous turnover, with the total oxygen exchange estimated at $\sim 15 \times 10^3$ Emol per 10^6 years. Aerobic life is responsible for the major portion of oxygen turnover, with photosynthesis being the main input into the oxygen reservoir, and respiration, the main output. The two processes are in approximate equilibrium, and fossil fuel combustion is the major source of oxygen loss from the reservoir.

The accumulation of dioxygen (O_2) in the earth's atmosphere allowed for the evolution of the enormous variety of aerobic organisms that use O_2 as the electron acceptor, thus providing a higher yield of energy compared with fermentation and anaerobic respiration.

4
Reactive Oxygen and Oxygen Toxicity

In its ground state (its normal configuration, O_2), molecular oxygen is relatively unreactive. However, during normal metabolic activity and as a consequence of various environmental perturbations (e.g. extreme temperatures, radiation, xenobiotics, toxins, air pollutants, various biotic and abiotic stresses, and diseases), O_2 is capable of giving rise to frightfully reactive excited states as free radicals and derivatives.

The oxidation powers of molecular oxygen are restricted because electrons can only be absorbed from another species whose electron spin is antiparallel to the two unpaired, parallel-spin electrons in diatomic oxygen. This spin restriction renders ground state molecular oxygen sufficiently unreactive, so that it cannot abstract electrons from other species. However, removal of the spin restriction by adding a single e^-, or upon transfer of energy to oxygen from a photosensitizer (e.g. chlorophyll; flavin-containing compounds), increases the reactivity of oxygen. Photosensitizers can harvest light and energize O_2 to form singlet oxygen ($^1\Delta_g O_2$), which can interact directly with another molecule, transferring the additional energy to the target molecule.

The complete reduction of O_2 to water requires four electrons. O_2 has a preference for a stepwise univalent pathway of reduction resulting in partially reduced intermediates (Fig. 1). The reactive species of reduced dioxygen include the superoxide radical ($O_2^{\bullet -}$), hydrogen peroxide (H_2O_2), and the hydroxyl radical ($OH^\bullet$). The latter can also be generated by the interaction of $O_2^{\bullet -}$ and H_2O_2 in the presence of metal ions. Both $O_2^{\bullet -}$ and $OH^\bullet$ are extremely reactive and can cause molecular damage leading to cell death. The hydroxyl radical reacts with virtually anything, inflicting indiscriminate and extensive intracellular damage. The $O_2^{\bullet -}$ is the conjugate base of a weak acid, the perhydroxyl radical (HO_2), whose pK_a is 4.69 ± 0.08. Thus, under acidic conditions, the very reactive perhydroxyl radical may predominate following a one-electron reduction of dioxygen, while at higher pH values the $O_2^{\bullet -}$ is predominant. These and the physically energized form of dioxygen, singlet oxygen ($^1O_2$) are the biologically most important ROS (Table 1). An activation energy of $\sim$22 kcal mol^{-1} is required to raise molecular oxygen (O_2) from its ground state to its first singlet state. In higher plants, this energy is readily obtained from light quanta via such transfer molecules as chlorophyll. Unless abated, all of these intermediate oxygen species are extremely reactive and cytotoxic in all organisms. ROS can interact with proteins, lipids, and nucleic acids to cause severe molecular damage (Table 2). Thus, oxygen provides a paradox in that it is essential for aerobic life and yet, in its reduced forms, it is one of the most toxic substances with which life on earth must

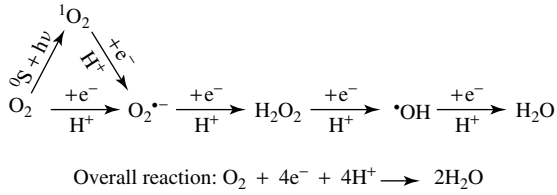

Fig. 1 Pathways in the univalent reduction of oxygen to water leading to generation of various intermediate ROS.

Tab. 1 Reactive oxygen species (ROS) of interest in oxidative stress.

Name	***Notation***	***Some comments & basic sources***
Molecular oxygen (triplet ground state)	O_2; $^3\Sigma$	Common form of dioxygen gas
Singlet oxygen (1st excited singlet state)	$^1O_2$; $^1\Delta$	Photoinhibition; UV irradiation; PS II e^- transfer Rx (chloroplasts)
Superoxide anion	$O_2^{\bullet -}$	Formed in many photooxidation Rx (flavoprotein, redox cycling); Mehler Rx in chloroplasts; mitochondrial e^- transfer Rx; glyoxysomal photorespiration; peroxisomal activity; nitrogen fixation; Rx of O_3 and OH^- in apoplastic space; defense against pathogens; oxidation of xenobiotics
Hydrogen peroxide	H_2O_2	Formed from $O_2^{\bullet -}$ by dismutation; photorespiration; β-oxidation; proton-induced decomposition of $O_2^{\bullet -}$; defense against pathogens
Hydroxyl radical	$OH^{\bullet}$	Decomposition of O_3 in apoplastic space; defense against pathogens; Rx of H_2O_2 with $O_2^{\bullet -}$ (Haber-Weiss); Rx of H_2O_2 with Fe^{++} (Fenton); highly reactive with all macromolecules
Perhydroxyl radical	$O_2H^{\bullet}$	Protonated form of $O_2^{\bullet -}$; Rx of O_3 and OH^- in apoplastic space
Ozone	O_3	UV radiation or electrical discharge in stratosphere; Rx involving combustion products of fossil fuels and UV radiation in troposphere

cope. ROS are found in virtually all intracellular organelles or compartments as a consequence of normal metabolic activity. Each organelle or compartment has potential targets for oxidative damage, as well as mechanisms for the elimination of excess ROS accumulation.

5 Defenses against Reactive Oxygen

To minimize the damaging effects of ROS, aerobic organisms evolved both nonenzymatic and enzymatic antioxidant defenses (Table 3). Nonenzymatic defenses include compounds of intrinsic antioxidant properties, such as vitamins C and E, glutathione, and β-carotene. Purely enzymatic defenses, such as superoxide dismutases (SOD), catalases (CAT), and peroxidases (Px) protect by directly scavenging superoxide radicals and hydrogen peroxide, converting them to less reactive species. Superoxide dismutases catalyze the dismutation of $O_2^{\bullet -}$ to H_2O_2, and catalases and peroxidases reduce H_2O_2 to $2H_2O$. The similarity between the SOD and CAT reactions is that each is an oxidation–reduction in which the substrate, $O_2^{\bullet -}$ for SOD and H_2O_2 for CAT, is both reductant and oxidant,

Tab. 2 Examples of ROS damage to lipids, proteins, and DNA.

Oxidative Damage to Lipids:
• Occurs via several mechanisms of ROS reacting with fatty acids in the membrane lipid bilayer leading to membrane leakage and cell death.
• In foods, lipid peroxidation causes rancidity and development of undesirable odors and flavors.
Oxidative Damage to Proteins:
• Site-specific amino acid modifications (specific AA differ in their susceptibility to ROS attack)
• Fragmentation of the peptide chain
• Aggregation of cross-linked reaction products
• Alteration in electrical charge
• Increase in susceptibility to proteolysis
• Oxidation of Fe-S centers by $O_2^{\bullet -}$ destroys enzymatic function
• Oxidation of specific AA "marks" proteins for degradation by specific proteases
• Oxidation of specific AA (e.g. Try) leads to cross-linking
Oxidative Damage to DNA:
• DNA deletions, mutations, translocations
• Base degradation, single-strand breakage
• Cross-linking of DNA to proteins

whereas different reductants are required for the peroxidases, depending upon their specificities. Under some conditions, CAT can act as an efficient peroxidase. SODs deal with the first product of the univalent reduction of O_2, converting it to H_2O_2, which must then be destroyed by catalases and/or peroxidases. Thus, the SODs and CATs serve, in tandem, as frontline antioxidant defenses:

$$O_2^{\bullet -} + O_2^{\bullet -} + 2H^+ \xrightarrow{\text{SOD}} O_2 + H_2O_2 (K_2 = 2.4 \times 10^9\ M^{-1}\ s^{-1})$$

$$H_2O_2 + H_2O_2 \xrightarrow{\text{CAT}} 2H_2O$$

$$H_2O_2 + R(OH)_2 \xrightarrow{\text{Px}} 2H_2O + R(O)_2 (K_4 = 0.2\text{–}1 \times 10^3\ M^{-1}\ s^{-1})$$

5.1 Superoxide Dismutase (SOD)

SODs have been isolated and characterized from a wide variety of organisms. One class consists of SODs with Cu(II) plus Zn(II) at the active site (Cu/ZnSOD), another with Mn(III) (MnSOD), a third with Fe(III) (FeSOD), and a fourth with Ni(II/III) (NiSOD). Cu/ZnSODs are generally found in the cytosol of eukaryotic cells, in chloroplasts, and in some prokaryotes; MnSODs are found in prokaryotes and in mitochondria; FeSODs are generally found in prokaryotes, in algae, and in some higher plant chloroplasts; NiSODs have been found in *Streptomyces*. Unlike most other organisms that have only one of each type of SOD in the various cellular compartments, plants have multiple forms of each type encoded by more than one gene, indicative that plants have far more complex antioxidant defenses. Plants also produce a large variety of small nonenzymatic antioxidant compounds as second tier defenses, such as glutathione, ascorbate, tocopherols, flavonoids, alkaloids, and carotenoids in high concentrations that are capable of quenching ROS. The dismutation of $O_2^{\bullet -}$ to $O_2 + H_2O_2$ by SOD is hardly a bargain, as the resulting H_2O_2 can react with metal ions, giving rise to the highly toxic $OH^{\bullet}$. Fortunately, catalases come to the rescue by degrading H_2O_2 to O_2 and H_2O. Most aerobes, including mammals, possess at least one form of homotetrameric catalase with ferriheme at the active sites.

Tab. 3 Some natural antioxidants.

(A) Nonenzymatic antioxidant molecules	
Antioxidant molecule	***Subcellular location***
Ascorbate (vitamin C)	Plastid; apoplast; cytosol, vacuole
β-carotene	Plastid
Glutathione, reduced (GSH)	Plastid; mitochondrion; cytosol
Polyamines (e.g. putrescine, spermine)	Nucleus; plastid; mitochondrion; cytosol
α-tocopherol (vitamin E)	Cell & plastid membranes
Zeaxanthin	Chloroplast

(B) Antioxidant Enzymes		
Enzyme	***EC Number***	***Subcellular Location***
Ascorbate peroxidase (APx)	1.11.1.11	Plastid stroma & membranes; cytosol
Peroxidases (nonspecific)	1.11.1.7	Cytosol; cell wall-bound; apoplast
Catalase (CAT)	1.11.1.6	Glyoxysome; peroxisome; cytosol; mitochondria
Superoxide dismutases (SOD)	1.15.1.1	Cytosol (*Cu/ZnSOD*); plastid (*Cu/ZnSOD;FeSOD*); mitochondrion (*MnSOD*); peroxisome (*Cu/ZnSOD*)
Dehydroascorbate reductase (DHAR)	1.8.5.1	Cytosol; plastid stroma
Glutathione reductase (GR)	1.6.4.2	Mitochondrion; cytosol; plastid stroma
Monodehydroascorbate reductase (MDHAR)	1.6.5.4	Plastid stroma
Glutathione *S*-transferases (GST)	2.5.1.18	Cytosol; Microsomal

5.2 Catalase (CAT)

CAT is largely, but not exclusively, localized in peroxisomes, wherein many H_2O_2-producing enzymes reside. Thus, catalase, which exhibits a high K_m for H_2O_2, can act upon the H_2O_2 produced before it diffuses to other parts of the cell. Catalase is a tetrameric heme-containing enzyme that is found in all aerobic organisms. Because of its wide distribution, evolutionary conservation, and capacity to rapidly degrade hydrogen peroxide, it has been proposed that CAT plays an important role in systems that have been evolved to allow organisms to live in aerobic environments.

Catalase is one of the most active catalysts produced by nature. It decomposes hydrogen peroxide at an extremely rapid rate, corresponding to a catalytic center activity of about 10^7 min^{-1}. Depending upon the concentration of H_2O_2, it exerts a dual function. At low concentrations ($<10^{-6}$ M) of H_2O_2, it acts "peroxidatically," where a variety of hydrogen donors (e.g. ethanol, ascorbic acid) can be oxidized in the following manner:

$$RH_2 + H_2O_2 \longrightarrow R + 2H_2O$$

At high concentrations of substrate, catalase decomposes toxic hydrogen peroxide at an extremely rapid rate using the ''catalatic'' reaction in which H_2O_2 acts as both an acceptor and donor of hydrogen molecules: $2H_2O_2 \rightarrow 2H_2O + O_2$.

Catalase is unique among H_2O_2 degrading enzymes in that it degrades H_2O_2 without consuming cellular reducing equivalents. Hence, catalase provides the cell with a very energy-efficient mechanism to remove hydrogen peroxide. Therefore, when cells are stressed for energy and are rapidly generating H_2O_2 through ''emergency'' catabolic processes, H_2O_2 is degraded by catalase in an energy-efficient manner. This results in a net gain of reducing equivalents and, therefore, of cellular energy. It has been proposed that catalase may be uniquely suited to regulate the homeostasis of H_2O_2 in the cell. In the catalatic mode, catalase has a very high apparent Michaelis constant and, therefore, is not easily saturated with substrate. Thus, the enzyme activity increases linearly over a wide range of H_2O_2 concentrations and, thereby, maintains a controlled intracellular H_2O_2 concentration. In mammalian systems, organs with high concentrations of catalase (i.e. liver and kidney) have low levels of endogenous H_2O_2 and organs with low concentrations of catalase (i.e. lung and heart) have high endogenous levels of H_2O_2. Further, if catalase activity is inhibited, H_2O_2 concentrations rise in the liver. As in the case of SOD, multiple catalases (isozymes), encoded by specific genes are found in plants, whereas animals exhibit one form of catalase. Both *Cat* and *Sod* genes respond differentially to various stresses known to generate ROS (Fig. 2).

6
ROS, Telomeres, and Aging

Many hypotheses have been proposed to explain the root cause of aging. One broad-based hypothesis is that generalized homeostatic failure leads to age-related decline. Another is the ''free-radical theory of aging'' suggesting that endogenous ROS continually damage cellular macromolecules, including DNA. Incomplete repair of such damage would lead to its accumulation over time resulting in age-related deterioration.

The evidence implicating the generation of ROS as key factors in determining longevity is accumulating. Much of the earlier evidence was correlative. However, recent evidence has identified longevity-influencing genes responsive to ROS. It has further been shown that continual induction of DNA damage during normal aging results in genomic instability due to persistent DNA lesions, mutations, stalled repair, and transcription interference. The involvement of ROS in limiting lifespan has been suggested by analyses of transgenic *Drosophila*, which systematically overexpress both *Sod* and *Cat* genes. Some strains of these transgenic flies live up to 30% longer than their natural counterparts, whereas flies carrying only one of these constitutively expressed transgenes do not live longer, suggesting that ROS toxicity plays an important role in longevity.

Much attention has also recently been given to the role of telomere shortening as a causative factor in aging/senescence. Telomeres are stretches of repetitive DNA of tandem short sequence repeats (TTAGGG) that ''cap'' the ends of eukaryotic chromosomes to protect against degradation. Telomeres, in most human cells, shorten with each round of DNA replication because they lack the

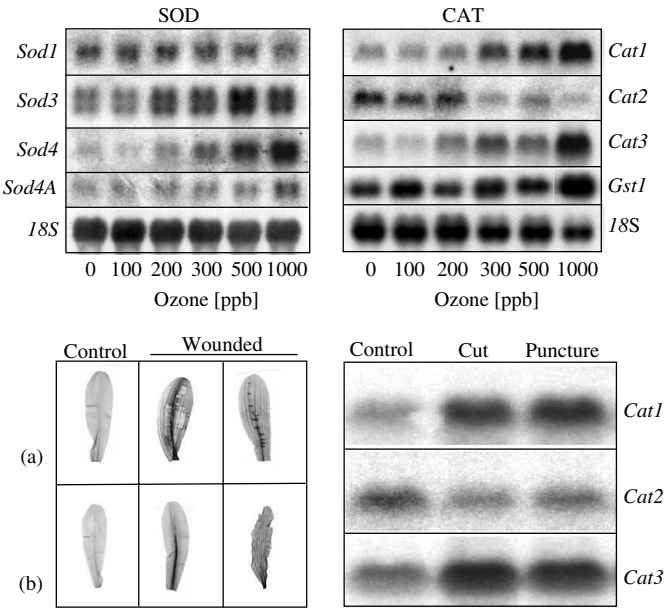

Fig. 2 Response to acute ozone exposure of the *Sod* (top-left) and *Cat* (top-right) genes in maize leaves after 6 h O_3 fumigation. As noted, some of the transcripts are upregulated (e.g. *Sod3, Sod4, Cat1, Cat3*), while others are downregulated (e.g. *Sod1, Cat2*). The 18S rRNA is a loading control. The production of H_2O_2 in maize leaves (bottom-left) in response to wounding. Seven-day-old plants were excised at the base of the stems and supplied with DAB (diaminobenzidine) for 6 h. The plants then were wounded and continuously supplied with DAB for 4 h. The production of H_2O_2 can be visualized by the deposition of the brown-red (dark areas) color products in the leaves. (a) Control and wounded leaves (wounding was conducted near the main vein), (b) control and wounded leaves (wounding was conducted at the main vein and cut at the leaf edges). *Cat* transcript accumulation in response to wounding (bottom-right). RNA was isolated from similarly treated leaves, indicative that differential transcript accumulation is effected by induction of H_2O_2. (See color plate p. xxv.)

enzyme telomerase. Telomerase is a specialized reverse transcriptase, which helps to replicate the telomere ends of chromosomes. However, telomerase is normally expressed only in germ-line cells and is derepressed in tumor cells in which telomeres are stabilized. It has recently been demonstrated that oxidative stress is the main reason for telomere shortening. It has been observed that H_2O_2 plus Cu(II) induced 8-oxo-7, 8-dihydro-2′-deoxyguanosine (8-oxodG) formation in the telomere sequences more efficiently than in nontelomere sequences. Oxidative damage is not repaired as well in telomeric DNA as elsewhere in the chromosome. Oxidative stress accelerates telomere loss, while antioxidants decelerate it. Thus, oxidative stress is a critical modulator of telomere loss and telomere-driven replicative senescence is primarily a stress response.

Given the available information, aging is likely a multifactorial process; whether ROS are peripheral targets that correlate with longevity or with central regulators of human aging remain to be resolved.

7 Oxidative Stress

Reactive oxygen species such as superoxide ($O_2^{\bullet -}$), hydrogen peroxide (H_2O_2), and hydroxyl radical ($OH^{\bullet}$) are produced in all aerobic organisms and normally exist in the cell in balance with antioxidant molecules. Oxidative stress occurs when this critical balance is disrupted because of depletion of antioxidants or excess accumulation of ROS, or both (Fig. 3). That is, when antioxidants are depleted and/or if the formation of ROS increases beyond the ability of the defenses to cope, then oxidative stress and its noxious consequences ensue. Such stress can happen when severely adverse environments or physiological conditions overwhelm biological systems. One rapid and clear indicator of oxidative stress is the induction of antioxidant defenses and/or increases in endogenous ROS levels. The formation of ROS can be accelerated as a consequence of various environmental stress conditions, including UV radiation, high light intensities, exposure to herbicides, extreme temperatures, toxins such as cercosporin and aflatoxin, air pollutants, metals, wounding, and xenobiotics. Many inducers of oxidative stress are known; carcinogens, mutagens, and toxins. It has become evident that ROS production is a common denominator in many diseases and environmental insults and can lead to

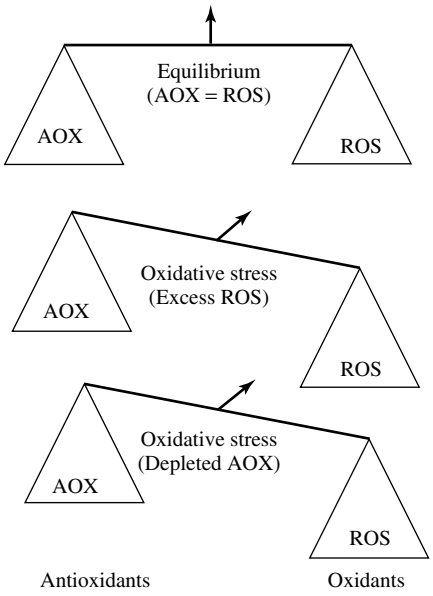

Fig. 3 Oxidative stress results from imbalance between the levels of antioxidants (AOX) and reactive oxygen species (ROS). Cells are normally able to balance the production of oxidants and antioxidants to maintain redox equilibrium. Oxidative stress occurs when this equilibrium is upset by excess levels of ROS, or depletion of antioxidant defenses.

severe cellular damage leading to physiological dysfunction and cell death in virtually all aerobes (Fig. 4).

When oxidative stress occurs, cells function to counteract the oxidant effects and to restore redox balance by resetting critical homeostatic parameters. Such cellular activity leads to activation or silencing of genes encoding defensive enzymes, transcription factors, and structural proteins.

8 ROS Can Serve Necessary and Useful Functions

It has recently become clear that ROS are not always harmful metabolic by-products as generally believed. When tightly regulated, ROS perform critical functions in the cell. In fact, a significant body of evidence indicates that ROS, particularly $O_2^{\bullet -}$ and H_2O_2, act as intracellular signaling molecules. In bacteria, the transcription factor OxyR activates a number of genes inducible by H_2O_2, while the transcription factors SoxR/SoxS mediate responses to $O_2^{\bullet -}$. Yeast also has two distinct adaptive stress responses, one directed toward H_2O_2 and one toward $O_2^{\bullet -}$. In higher eukaryotes, both animals and plants, oxidative stress responses are more complex and are modulated by several regulators. ROS-dependent redox cycling of cysteinyl thiols is critical for establishing protein–protein and protein–DNA interactions that determine many aspects of signal transduction pathways by regulating the activity of many transcription factors. For example, activation of nuclear factor κB (NFκB) and activator protein-1 (AP-1), known to have critical roles in proliferation, differentiation, and morphogenesis, can result from stimulation by diverse agents proceeding through a common pathway involving ROS generation. The pathway leading to H_2O_2 production and subsequent redox activation of NFκB has been shown to

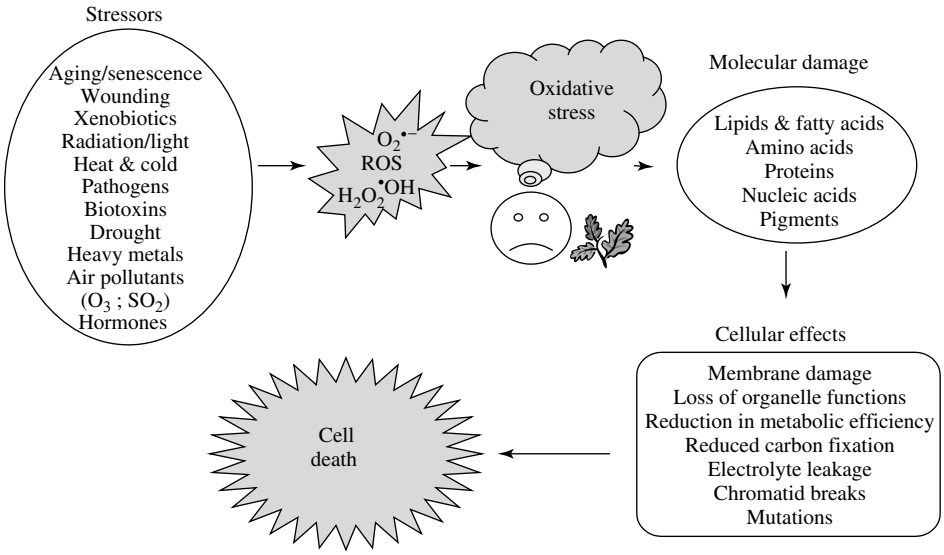

Fig. 4 Scheme showing some of the initiators (stressors) of ROS and the biological consequences leading to a variety of physiological dysfunctions that can lead to cell death.

involve the Rho family of small GTP-binding proteins.

Both intracellular and extracellular sources of ROS are capable of modulating gene expression. Low doses of H_2O_2 (<20 μM) can elicit changes in phosphorylation of specific regulatory proteins including protein kinase B (AKT). Direct signaling action of H_2O_2 in the differential regulation of antioxidant genes in plants likely occurs via protein–DNA interactions in the region of the antioxidant responsive element (ARE; TGACTCA), NFκB, and ABA responsive element (ABRE-2; ACGT) in the promoters of these genes. In addition to induction of defense gene expression, other roles of ROS in plants include direct killing of pathogens, involvement in cell wall structure, and promotion of programmed cell death. In yeast and animal cells, ROS have been shown to arrest cell division, and cell cycle progression is under negative ROS control. A clear and powerful example of how ROS are put to constructive use was the observation that $O_2^{\bullet -}$ plays an important role against invading microbes, in effect serving as a broad-spectrum antibiotic. In response to invasion by pathogens, plants also mount a broad range of defense responses, including a rapid and transient production of large amounts of ROS (''oxidative burst'').

Thus, ROS play different, or even opposing roles, during different cellular processes (Fig. 5). For example, under physiological conditions, H_2O_2 may play an important role in signal transduction pathways and in activation of the transcription factor NFκB, while under pathologic (stress) conditions, H_2O_2 can lead to apoptosis or necrosis. Consequently, the steady state level of ROS within cells is critical and is determined by the interplay between ROS-generating mechanisms and the subtle modulating roles played by cellular antioxidants. In plants, H_2O_2 is generated under a diverse range of biotic and abiotic conditions, and its accumulation in specific tissues at specific developmental times, in the appropriate quantities,

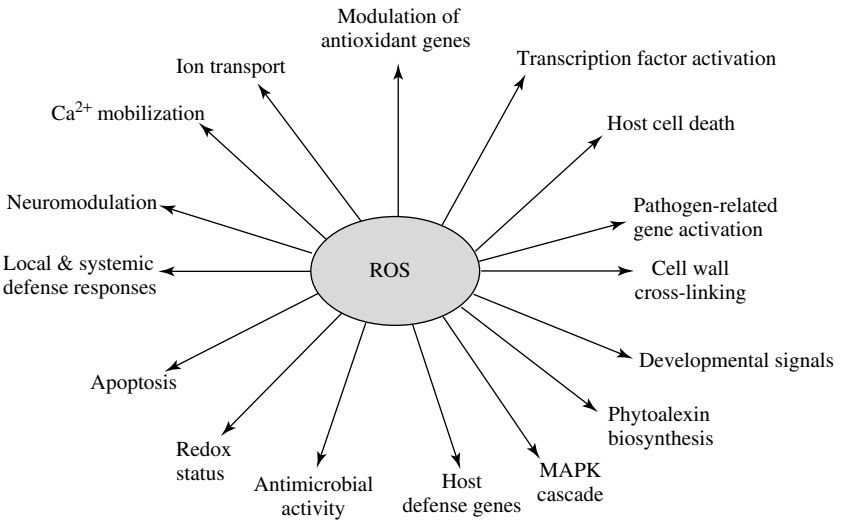

Fig. 5 Scheme showing some of the useful pleiotropic roles of ROS known to occur in most higher organisms, indicative of the fact that ROS are not always harmful to cells.

benefits plants and can mediate cross-tolerance to other stresses. H_2O_2 affects gene expression and activates MAP kinases, which in turn function as regulators of transcription.

9 Oxidative Stress and Gene Expression

Although observations have led to the suggestion that cells have the means to sense ROS and to induce specific responses, the underlying mechanisms are still not fully understood. The transcriptional network that responds to ROS in eukaryotes is currently being deciphered, whereas the prokaryotic system is better understood.

Nearly two decades ago, it was shown that the expression of ~30 proteins were induced by H_2O_2 in bacteria. Of these 30 proteins, 12 were maximally induced within 10 min and 18 between 10 and 30 min. The OxyR regulatory protein was subsequently shown to regulate expression of 9 of the 12 rapidly induced proteins. The tetrameric OxyR protein is a member of the LysR family of transcription activators and exists in two forms, reduced and oxidized; only the oxidized form is able to activate transcription. Further studies led to the identification of a number of OxyR-activated genes. Similarly, the SoxRS regulatory proteins were found to regulate expression of $O_2^{\bullet -}$-responsive proteins in bacteria. Regulation of the *SoxRS* regulon occurs by conversion of SoxR to an active form that enhances *soxS* transcription. The enhanced levels of SoxS in turn activate expression of the regulon. In addition to SoxR and OxyR, several other transcriptional regulators modulate the expression of antioxidant genes in bacteria, indicative of the complexity and connectivity of overlapping regulatory networks. No apparent homologs of OxyR, SoxR, or SoxS have been found in eukaryotes, but a number of other transcription factors have been found to play a role in regulating the expression of antioxidant genes in eukaryotes. In yeast, transcription regulators of antioxidant genes include ACE1, MAC1, YAP1, YAP2, HAP1, and HAP2/3/4. In higher eukaryotes, oxidative stress responses are more complex and are modulated by several different regulators. In mammalian systems, NFκB and AP-1 are involved in regulating the oxidative stress response. The "antioxidant responsive element" (ARE), present in the promoter region of mammalian glutathione *S*-transferase (GST), metalothionein-I, and Mn*Sod* genes, causes induction of these genes in response to oxidants. NFκB, AP-1, and ARE have also been found in promoters of antioxidant genes in higher plants (Fig. 6). The role of these factors is not unique to activation of antioxidant genes, as they are known (particularly NFκB) to play central roles in regulating cellular responses to other stresses as well as regulating normal growth and metabolism.

There is substantial evidence that a variety of biotic and abiotic stresses induce ROS, which serves as a common factor in regulating various signaling pathways (Fig. 7). Similar stresses also activate mitogen-activated protein kinases (MAPK)s with kinetics that either precede or parallel H_2O_2 production, suggesting that MAPKs may be one of several converging points in the defense-signaling network. In addition, exogenous application of several plant hormones and toxins has been shown to induce $O_2^{\bullet -}$ and H_2O_2 synthesis, leading to differential induction of some antioxidant genes and isozymes

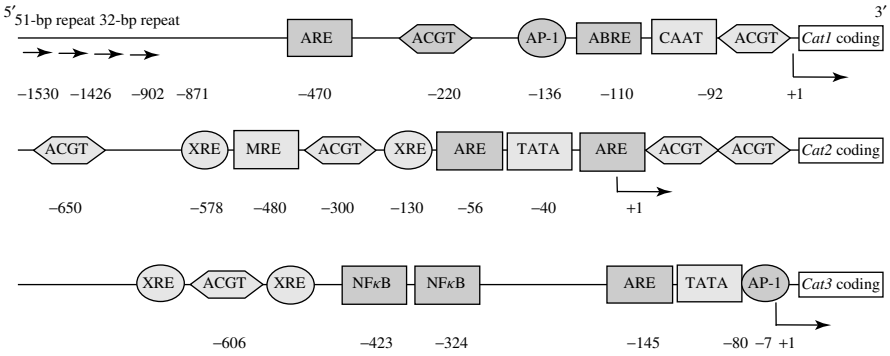

Fig. 6 Schematic representation of the promoter region of each of the three catalase (*cat*) genes of maize indicating the locations of the NFκB, ARE, AP-1, and ABRE motifs relative to the transcription start site (+1) of each gene.

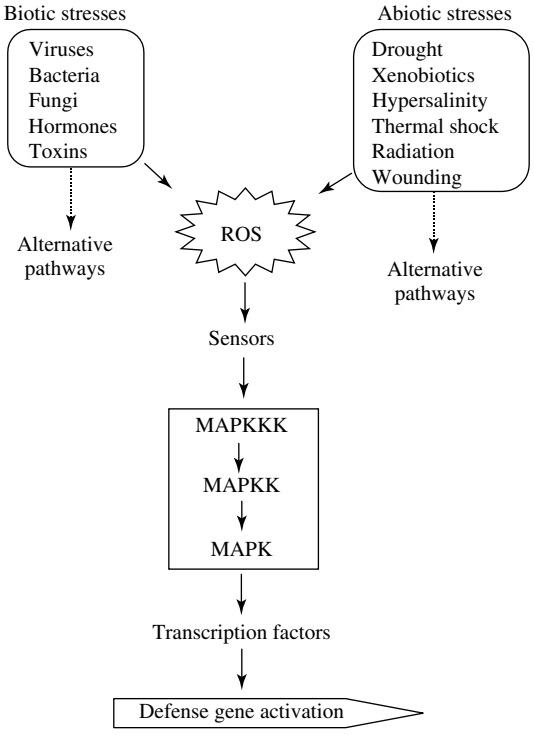

Fig. 7 Convergence of various biotic and abiotic stress stimuli onto MAPK pathways via ROS as a common factor, leading to activation of antioxidant defense genes. Alternative pathways have also been implicated.

(Fig. 8). Thus, the identification of all genes and proteins regulated by H_2O_2 is an important step toward treatments that might confer tolerance to multiple, but interrelated, stresses. In addition to induction/repression of antioxidant defense genes, ROS are known to similarly affect expression of a variety of other genes involved in different signaling pathways in microbes, yeast, plants, and animals.

10 Genomic Scale ROS-Responsive Gene Expression

The advent of microarray expression analysis makes possible the assessment of gene expression on a genomic scale, rendering tens of thousands of genes assayable in a single experiment. Thus, identification of ROS-responsive genes on a global scale is now tenable. DNA microarrays can comprehensively examine gene expression networks during oxidative stress. There is now significant progress being made in surveying gene expression in response to H_2O_2 in *Escherichia coli*, yeast, and higher plants.

A genome-wide transcription profile of *E. coli* cells exposed to H_2O_2 was examined with a DNA microarray composed of 4169 *E. coli* open reading frames. Gene expression was measured in isogenic wild type and *oxyR* deletion mutants ($\Delta oxyR$) to confirm that the H_2O_2-response regulator OxyR activates most of the H_2O_2-inducible genes. A very rapid and strong induction was observed of a set of OxyR-regulated genes in the wild type but not in the $\Delta oxyR$, providing internal validation of the experiment and confirmation for the induction of the oxidative stress genes identified earlier by other means. Several new H_2O_2-inducible genes were also identified: some were members of the OxyR regulon and some were induced by an OxyR-independent mechanism suggestive of other H_2O_2 sensors and regulators in *E.coli*. Several genes repressed by OxyR were highly expressed in the $\Delta oxyR$ mutant. Overall, the mRNA of 140 genes in the wild type, and 167 genes in the $\Delta oxyR$ were significantly induced after H_2O_2 treatment. It was also found that *soxS* was induced by H_2O_2, indicating an overlap with other regulatory pathways. Two genes, *Fpr* and *sodA*, known to be members of the SoxRS regulon were also highly induced by H_2O_2 in both wild type and $\Delta oxyR$. The microarray data also showed an overlap between oxidative stress, heat shock, and SOS responses. The results from the *E. coli* microarrays clearly indicate that the activities of transcription

factors in addition to OxyR and SoxRS are likely modulated by oxidative stress.

Whole-genome expression patterns in *Saccharomyces cerevisiae* cells exposed to H_2O_2, in addition to other stresses, indicated that about two-thirds of the genome is involved in the response to environmental changes, and the global set of genes induced/repressed by each environmental signal were identified. The response to oxidative stress involves about one-third of the yeast genome and the maximal effects on gene expression occur slightly later, relative to other stresses examined during similar time courses, with most of the transcriptome returning to prestress levels within 2 h following exposure to H_2O_2. Genes that are repressed for ~60 min after exposure to H_2O_2 are only transiently repressed in other stress time courses. Thus, genes encoding the translation apparatus and its regulators are remarkably coordinated for each environmental change, although the dynamics of each response are different. The expression programs following H_2O_2 or $O_2^{\bullet -}$ treatment were essentially identical despite the fact that different ROS are involved. There was strong induction of genes known to be involved in detoxification of both H_2O_2 and $O_2^{\bullet -}$, such as catalase, superoxide dismutase, and glutathione peroxidase, as well as genes involved in oxidative and reductive reactions (e.g. thioredoxin, glutathione reductase, glutaredoxin). The genes most strongly induced in response to H_2O_2 and $O_2^{\bullet -}$ were dependent on the transcription factor Yap1p for their induction. Genes moderately induced by ROS and other signals are regulated by different transcription factors, depending on the conditions, and different upstream signaling pathways may govern their response. It has also been demonstrated that in *Schizosaccharomyces pombe*, H_2O_2 activates the Sty1 (stress-activated mitogen-activated protein kinase, MAPK) pathway in a dose-dependent manner via two sensing mechanisms. At low H_2O_2 levels, a two-component signaling pathway, which feeds into either of the two (Wak1 or Win1) stress-activated mitogen-activated protein kinase kinase kinases (MAPKKKs) regulates Sty1. At high H_2O_2 levels, however, Sty1 activation is controlled mainly by an independent two-component mechanism, which requires the function of both Wak1 and Win1. In addition, the individual bZip transcription factors, Pap1 and Atf1, were found to function within a limited range of $[H_2O_2]$: Pap1 activates target genes at low $[H_2O_2]$, whereas Atf1 controls transcriptional responses to high $[H_2O_2]$, with some minor overlap. Some apparent cross talk among Sty1, Atf1, and Pap1 has been detected. Thus, *S. pombe* deploys a combination of stress-responsive regulatory proteins to gauge and trigger the appropriate transcriptional response to increasing H_2O_2 concentrations. This organism mounts two separate responses to oxidative stress – an adaptive response to low-level H_2O_2 exposure that protects it from subsequent exposures to higher $[H_2O_2]$, and an acute response that allows the cell to survive a sudden, potentially lethal dose of H_2O_2.

Large-scale cDNA microarray analysis of the *Arabidopsis* transcriptome during oxidative stress identified 175 nonredundant expressed-sequence tags (ESTs) from a sample of 11 000, which are regulated by H_2O_2. Of these, 62 are repressed and 113 are induced. In addition, RNA blots showed that some of the H_2O_2-regulated genes are also modulated by other signals known to involve oxidative stress. Furthermore, a substantial portion of these genes have predicted functions in defense response, cell rescue and signaling, and transcription, underscoring the

pleiotropic effects of H_2O_2 in the response of plants to stress. Overall, the microarray used was estimated to represent only ~30% of the *Arabidopsis* genome, depending on redundancy, and 1 to 2% of the genes represented in the array are affected by H_2O_2-imposed oxidative stress, being comparable to the situation in yeast. Of the 175 genes identified as H_2O_2-responsive, most have no obvious direct role in oxidative stress but may be linked to oxidative stress indirectly, as a consequence of other biotic and abiotic stresses, explaining their sensitivity to H_2O_2. Among the genes induced by H_2O_2 were genes encoding transcription factors, suggesting that they may mediate downstream H_2O_2 responses. As in other organisms, expression of the MAPKs in *Arabidopsis* is induced by oxidative stress, which in turn can mediate the induction of oxidative stress-responsive genes.

11 Approaching an Integrated View of Stress Responses

The traditional view of ROS as mere indiscriminate, reactive by-products of cellular metabolism has recently undergone a metamorphosis. This view came about by the discovery that ROS may act as signal-transducing molecules and that activation of intracellular transcription factors such as OxyR, SoxRS, NFκB, and AP-1 occur via interaction with ROS, leading to gene transcription (Fig. 9).

Genome sequencing and expression profiling using DNA or oligonucleotide microarrays and related technologies, have been used effectively in the study of global gene expression patterns in response to different growth and environmental conditions to which organisms are exposed. Subsequent hierarchical clustering methods allow for the allocation of genes, coregulated temporally or in response to a given signal, into specific expression groups or regulons. The numbers of genes that can be detected by these methods in response to any given environmental or developmental signal far exceed the limited number that could have been detected only a few years ago. With the current methods, the expression of tens of thousands of genes can be detected in a single experiment in response to ROS, or to any given signal. Since transcription of genes into mRNA is governed by transcription factors that bind to cis-regulatory regions of the DNA in the vicinity of the target gene, the question arises as to whether large coregulated groups of genes share cis-regulatory elements that bind to common transcription factors. The data available with respect to oxidative stress seem to suggest this. Cis-acting elements within the promoters of ROS-activated genes are being defined as well as their cognate trans-acting factors. A comparative analysis of promoter sequences of genes with similar expression profiles should provide a basis for unraveling common regulatory sequences and overlapping gene expression networks modulating ROS-responsive genes. The antioxidant enzymes catalase and superoxide dismutase play key roles in modulating the levels of endogenous H_2O_2 and $O_2^{\bullet -}$, which at specific concentrations act to, in turn, modulate the expression of other ROS-responsive genes.

The use of microarrays and future derivations thereof, to examine global gene responses to ROS is assured. It has become clear that there are far more genes and gene clusters responding to ROS than previously thought, and that ROS likely play far more key roles in cellular activities than anticipated. As global gene

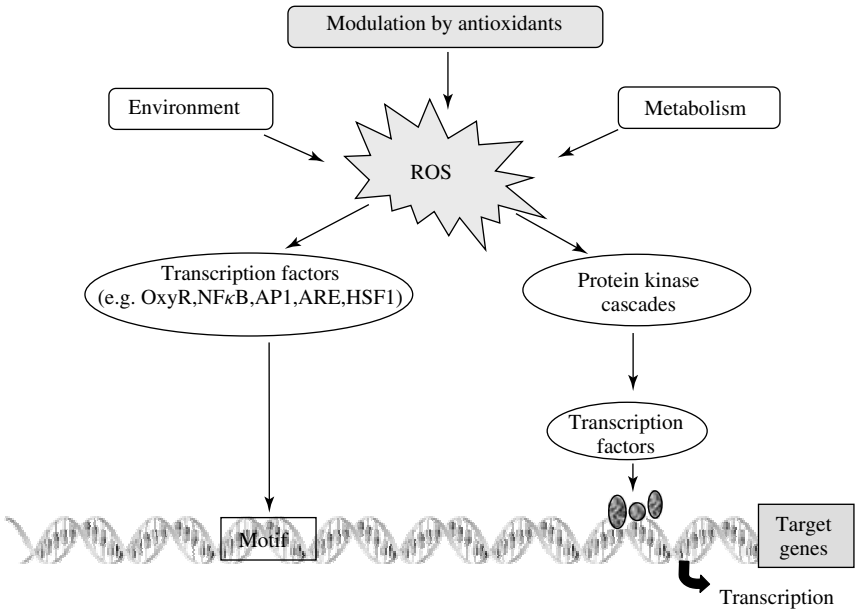

Fig. 9 The major signaling pathways activated in response to oxidative stress. ROS originating from environmental signals or from metabolic activity are modulated by antioxidants to nontoxic levels at which point they serve as signaling molecules. ROS can activate gene transcription in two ways: (1) via transcription factors, such as NFκB, AP-1, and ARE-binding proteins (ARE-BP) that can interact directly with specific DNA motifs on promoters of target genes, or (2) via activation of MAPK cascades, which in turn activate transcription factors that trigger target gene transcription. The degree to which a given pathway is activated depends on the nature and duration of the stress, as well as on cell type and developmental stage.

responses to ROS are examined temporally and spatially along with different time courses and varied oxidant concentrations, even more complex regulons and regulatory cascades will emerge. It will also be instructive to examine gene expression profiles in specific mutants to help delineate the roles of specific regulators and of ROS. The identification of alternate pathways of ROS-dependent gene expression and characterization of the redox-sensing mechanisms involved should point to new insights and directions. Some genes have been identified whose transcription is responsive to a variety of stresses in addition to oxystress, while others appear to be responsive only to ROS or other specific signals. Although some regulatory systems have been implicated in modulating such responses, the complete network of regulators of ROS responses that activate such genes remains unclear.

Microarray results from different organisms clearly underscore the fluidity of genomes to reorganize and respond to changes in the cellular and extracellular environment. However, characterization of global gene expression programs at the transcript level is only the first step toward defining the role or function of each ROS-responsive gene. It is not unlikely that small changes in gene expression could

lead to large alterations in protein levels. Consequently, proteomic analyses are essential to correlate mRNA changes with protein levels. There is, in fact, ample data demonstrating that ROS can alter the activity of cellular proteins.

A large and growing number of sequenced genomes and emerging technologies present us with enormous opportunities to advance biological science and our knowledge of how genomes perceive signals to respond to variable environments. Oxidative stress and the responses to it seem to be central to many of the key biological questions. However, as the euphoria of new sequencing and technological advances begin to fade, we must recognize the magnitude of the problems that still need to be solved. Knowing the sequences of tens of thousands of ROS-responsive genes only reminds us that we still do not know the many proteins they encode, nor the biochemical or biological function of the great majority of such proteins. How such proteins interact with ROS to drive the various physiological processes in aerobic organisms remain a great puzzle. For the future, the fundamental challenge will be to integrate the information now being obtained on gene expression patterns with structural, topological, and functional parameters and interactions of the various proteins encoded by ROS-responsive regulons, and to view the cell in which they function holistically.

12 The Paradox

The oxygen paradox is indeed the paradox of evolution itself. Evolutionary pressures have made the best of a bad situation by generating mechanisms to curtail the undesirable toxic effects of ROS, which are an unavoidable consequence of the aerobic lifestyle, and to put them to constructive uses. Indeed, evolution has coopted ROS to serve necessary and useful purposes in the maintenance of cellular homeostasis and in the communication of cells with the external environment. The focus must now be placed toward a more thorough understanding of how ROS-mediated signals are perceived, transduced, and interpreted by the cell's genetic machinery. Perhaps the most noteworthy observation to date concerning oxidative stress and its negative and positive roles is its universality among aerobic organisms and the similarities emerging in the regulatory mechanisms underlying their roles in all species.

The classical view of ROS as villains that indiscriminately destroy biomolecules has undergone a shift in which positive biological roles are considered as well. It is now accepted that ROS, particularly H_2O_2 and $O_2^{\bullet -}$, are carefully regulated metabolites capable of signaling and communicating critical information to the cell's genetic machinery. Redox regulation of gene expression by oxidants and antioxidants is emerging as a vital mechanism in the health of all eukaryotes, including man.

It would indeed be interesting and challenging to identify all the changes in gene expression regulated by oxidative stress, and to determine their commonality among diverse species. Such a global analysis of the effects of H_2O_2 and $O_2^{\bullet -}$ on the transcriptome of eukaryotes has not yet been attained, but with the emergence of postgenomic technologies it will likely be not far off.

13 Genomic Fluidity

There are programmed responses to stress that are initiated within the genome itself,

which can lead to new and irreversible genomic modifications. Thus, in many organisms, the genome may reorganize itself on facing an adversity for which it is unprepared in order to ensure the organism's survival. For example, cells are able to sense the presence in their nuclei of ruptured ends of chromosomes and then to activate mechanisms that will bring together and then unite these ends, one with another. This is the most revealing example of the sensitivity of cells to what is occurring within them.

The capacity of the genome to reorganize and respond rapidly ("genomic fluidity") was solidified by the pioneering work of Barbara McClintock, who demonstrated that discrete genetic loci could transpose in the genome of maize, and was subsequently shown to occur universally among all organisms. Genomic flexibility is an extraordinary adaptability of organisms to their environment. In the course of evolution, those organisms that had the capacity to adapt to new environments survived. This capacity was due to the ability of each organism or species that survived, to possess in its biological repertoire the means to cope with environmental adversity. In situations in which multiple environments existed, those organisms that possessed motility (e.g. animals) could exchange one environment for another; those with a stationary lifestyle (e.g. plants) had to rely on alternate defenses; a case in point being the far more complex, genetically and biochemically, antioxidant defenses in plants versus their animal counterparts. However, in adverse environments (natural or anthropogenic) from which organisms cannot escape, they must rely on diverse and unique sets of responses encoded within, or resulting from the flexibility of their genome. Environmental stress itself can instigate genome modifications by mobilizing cell mechanisms that can restructure genomes in various ways. A novel example is the restructuring of the host genome by plant galls. In this case, one organism is forced to produce a wholly new structure for the benefit of another. The exact structural organization of a given gall gives it a uniqueness that begins with an initial stimulus characteristic of each invasive species. The galls on legume roots associated with nitrogen-fixing bacteria provide a clear example of reprogramming of the plant (legume) genome by a stimulus received from a foreign organism (bacteria). In other examples, a single plant may have several distinctly different galls on its leaves, each catering to a different insect species. The stimulus for placing the insect egg into the leaf initiates reprogramming of the plant's genome, forcing it to make a unique structure adapted to the needs of the developing insect. Such genomic reprogramming induced by a variety of organisms, including bacteria, fungi, and insects, are not a requisite response of the plant host genome during its normal developmental cycle. Interestingly, gall formation involves upregulated levels of ROS and of antioxidant defense genes. Such genomic reorganization allows the organism to cope with stress, and in the long term may provide the bases for evolution of new species.

As the genome of various organisms is being investigated with state-of-the-art molecular techniques, more knowledge is being gained on the structural components involved in the response of specific genes to environmental insult. However, we are just beginning to learn about how the cell perceives danger and initiates the truly remarkable observed responses to it. Once such

information is available, and a better understanding of the defense response is attained, the engineering of organisms for resistance or sustained tolerance to various adverse environmental stresses will be possible.

A signal transduction pathway contains elements that enable a signal to be transmitted within and between cells and to be translated into an appropriate response. Cells can respond to a variety of environmental, physical, and chemical stimuli using a diverse range of transduction and response mechanisms. The essential features of a signal transduction pathway comprise a *receptor* (recognition element) capable of detecting a stimulus, *second messengers* (transmission elements) such as calcium or phosphorylation cascades, and *response elements* (e.g. gene transcription). Such signaling networks are now amenable to study and dissection by biochemical and genetic approaches that may elucidate the underlying mechanisms and lead to the identification of the molecules responsible. A thorough understanding of how organisms perceive, respond, and adapt to changing environmental and developmental stimuli is now attainable.

14 Conclusions

The survival of organisms on earth depends upon the interactions of their genomes with the environments in which they exist. In the course of evolution, organisms evolved a complex array of mechanisms for adapting to both minor and major fluctuations in the environment. The emergence of oxygenic photosynthesis presented early life forms with the greatest environmental challenge and an opportunity. The challenge was to develop antioxidant defenses in order to survive; the opportunity was to exploit the reactivity of oxygen for energy yielding and biosynthetic reactions. The opportunity led to the highly diversified life forms that evolved sufficient defenses and managed to exploit the aerobic lifestyle. Oxygen toxicity likely led to massive extinctions of those organisms unable to cope with it, unless they took refuge in isolated anaerobic niches. Thus, oxygen is a ''double-edged sword'' in that it makes life on earth possible, but in its reduced forms (reactive oxygen species, ROS), it is highly toxic and lethal. Oxidative stress can arise from an imbalance between generation and elimination of ROS leading to excess ROS levels inflicting indiscriminate damage to virtually all biomolecules leading to various diseases and cell death. The notion that ROS are merely toxic by-products of O_2 metabolism has recently been altered by experimental evidence indicating that ROS are carefully regulated metabolites capable of signaling and communicating information to the cell's genetic machinery. Redox regulation of gene expression by oxidants and antioxidants is emerging as a vital mechanism in the health and disease of all organisms. Irrespective of how or when ROS are generated, an increase in intracellular oxidants results in two critical effects: damage to various cell components and activation of specific signaling pathways, influencing various cellular processes leading to proper cell functions or to cell death. Genomic tools are accelerating the discovery of ROS-responsive genes on a global scale and are expanding our understanding of the oxidative stress response and the pleiotropic roles of ROS in signaling and gene expression.

ISBN: 3-527-30547-5

Bacterial Artificial Chromosome (BAC)
A single-copy plasmid cloning system for large DNA molecules (100–300 kb).

Base-calling
Derivation of nucleotide assignments from sequencing chromatograms.

Fingerprinting
Enzymatic restriction of large-insert clones electrophoretically separated and viewed on an agarose gel.

Genetic Map
A set of genetic markers ordered by their recombination frequencies.

Genome
The complete complement of DNA for an organism consisting of all genes and organized on one or more chromosomes.

Physical Map
An ordered set of large-insert clones providing a physical coverage of a genome.

Production or Shotgun Sequencing
A generation of redundant, raw sequence data from random subclones of a longer target clone.

Beginning with the landmark work of Watson and Crick and continuing with the technological breakthroughs of the 1970s, 1980s, and the 1990s, molecular genetics and genomics has revolutionized all aspects of biology. Today, scientists are able to decipher the precise order of every nucleotide of an organism's complete genome, using a conceptually simple approach called *shotgun sequencing*. Briefly described, shotgun sequencing involves randomly breaking the target genome into smaller pieces, which are sequenced and reassembled into a complete sequence using computer software. Genome sequences provide a basis for further research into gene regulation, pathology, evolution, and metabolism. In order to appreciate a complete genome sequence for the experimental data that it is, it is necessary to review the steps taken to generate genomic sequence. This article will review both the technical aspects of genome sequencing as well as the various strategies employed for sequencing large, eukaryotic genomes.

1
Introduction to Genome Sequencing

The history of modern genomics developed from a fusion of genetics, cytogenetics, biochemistry, and molecular biology. Each of these fields has contributed to our understanding of the material basis of inheritance and how genes code for organismal phenotypes. We may briefly define a genome as the complete set of DNA for a given organism, organized into chromosomes and containing all the genes, which code for the organism's traits (Fig. 1). Thus, historically separate fields of study find union in genomics, the study of organismal genomes. Genome sequencing represents one of the most fundamental steps in genomic analysis. To sequence a genome is to decipher the precise order of nucleotides (the sequence) of that genome. Genome sequencing serves as a foundation for future analyses of gene regulation, chromosome structure, genetic pathologies, and evolution.

With the historic deciphering of the chemical structure of DNA by Watson and Crick in 1953, the modern era of molecular biology and genomics began in earnest. Efficient methods of DNA sequencing were introduced in the 1970s, and the complete 16 569 bp human mitochondrial genome sequence was published in 1980. By the middle of the 1980s, researchers were already beginning to discuss the feasibility of deciphering the sequence of the entire human genome, and the official Human Genome Project began in 1990. The successful application of shotgun sequencing to bacterial genomes by the Institute for Genomic Research in the mid-1990s ushered in a period of rapid expansion of genome sequencing. Today, the complete genomes of more than 100 bacteria and archaea have been sequenced, together with several eukaryotes. Two different drafts of the human genome sequence were published in 2001, and the human genome sequence was completed in 2003.

Despite the enormous changes wrought on modern biology by genomics, the basic techniques of DNA sequencing have not fundamentally changed in the 30 years since their development. This article will begin with an overview of Sanger's sequencing technique and the shotgun strategy utilized in modern genome-sequencing projects. We will then discuss strategies for obtaining the sequence of large genomes, including the hierarchical mapping/sequencing method and the whole-genome shotgun (WGS) that has recently become popular for sequencing eukaryotic genomes. The article will conclude with a brief summary of methods for identifying biological features in raw DNA sequence data.

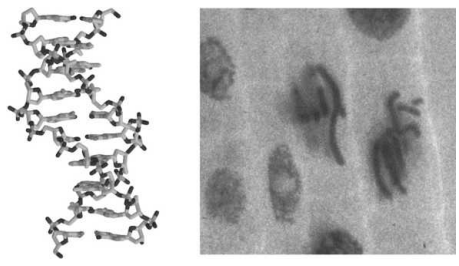

Fig. 1 An organism's genome is the complete complement of DNA, (a) consisting of all genes and (b) organized into chromosomes.

2 The Sequencing Technique

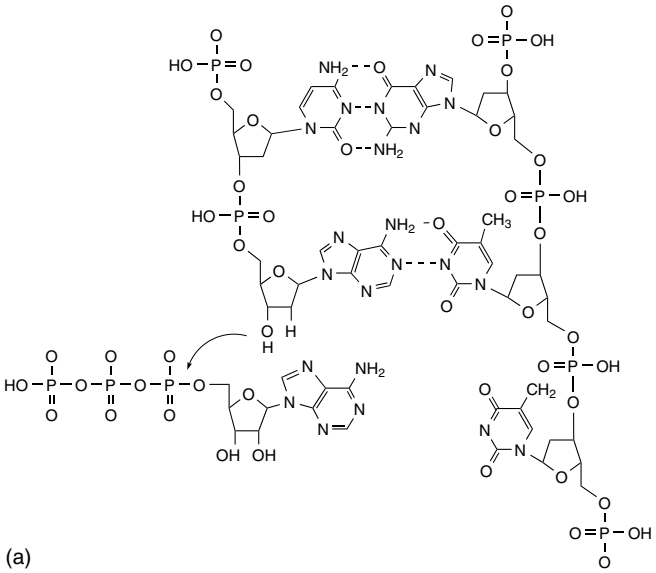
The basic sequencing technique developed in the 1970s begins with the polymerization of synthetic strands of DNA from a template strand. The template strand is a cloned piece of DNA that originates from the organism of interest (see below). The polymerization of the synthetic strand of DNA takes place in a mixture of normal deoxynucleoside triphosphates (dNTPs) and a dideoxynucleoside triphosphate (ddNTP). ddNTPs lack a 3′ hydroxyl but in all other ways are identical to normal dNTPs. They can substitute for normal dNTPs in DNA polymerization reactions, but the missing 3′ hydroxyl prevents elongation of any DNA strand when a ddNTP is incorporated (Fig. 2). As a result, the chain terminates at ddNTP incorporation, giving ddNTPs their colloquial name ''chain terminators.''

Chain terminators are used in sequencing by including a small amount of them in a synthetic DNA polymerization reaction. The result is random incorporation of chain terminators into growing DNA strands, yielding a complete set of fragments that begin at the same 5′ end but terminate at 3′ positions where a chain terminator has been incorporated (Fig. 2). For example, when ddATP is included in synthetic DNA polymerization, the resulting strands will vary in length but all will terminate at the 3′ end with an adenine. Using the other three ddNTPs, fragments can be generated that terminate with a known base at the 3′ end of the fragment (Fig. 3).

Chain-terminated fragments are then size-fractionated by electrophoresis on a polyacrylamide slab gel. Because the gel has a very fine pore size, fragments differing in length by a single nucleotide can be separated. This allows each chain-terminated fragment to be distinguished on the polyacrylamide gel. Traditionally, fragments in the gel were visualized by incorporating radioactively labeled dATP in the sequencing reactions and exposing the gel to X-ray film after electrophoresis.

One of the major innovations that rendered genome sequencing practical is the introduction of fluorescent labels, which alleviated the need for radioactive dATP and X-ray film. In fluorescent sequencing, the DNA fragments corresponding to the four different ddNTP chain terminators are labeled with a different fluorescent tag. These tags are excited by a laser at the end of the gel and the fluorescent light is detected at the different wavelengths of each of the four dyes. Detection of the fluorescent tags can take place as the electrophoresis is still occurring, eliminating the need to stop the electrophoresis and expose the gel to X-ray film. For fluorescent tags attached to the sequencing primer (dye-primer), the four sequencing reactions corresponding to the four bases must occur in isolation. Alternatively, fluorescent tags can be attached directly to the ddNTP (dye terminator), which allows for a single sequencing reaction in a single container for each template to be sequenced. Generally, dye-terminators reduce the frequency of anomalous mobility during electrophoresis but are poorly recognized by the DNA polymerase, presumably because of the added bulk of the attached fluorescent dye. Dye primers, while requiring isolated preps and an extra mixing stage prior to electrophoresis, provide a consistently readable signal.

A record of fluorescent tags as they pass by the detector during electrophoresis is called a *sequence trace*. A trace can be converted to a visual representation called a *chromatogram* (Fig. 4) for translation



(a)

into a nucleotide sequence. Translation of a chromatogram into a sequence is called *base calling*. In the chromatogram, nucleotides correspond to peaks of fluorescence, which are displayed with different colors representing different nucleotides. Because of the obvious need for rapid base calling in large-scale genome projects, software has been developed to automate the process. There are several base-calling

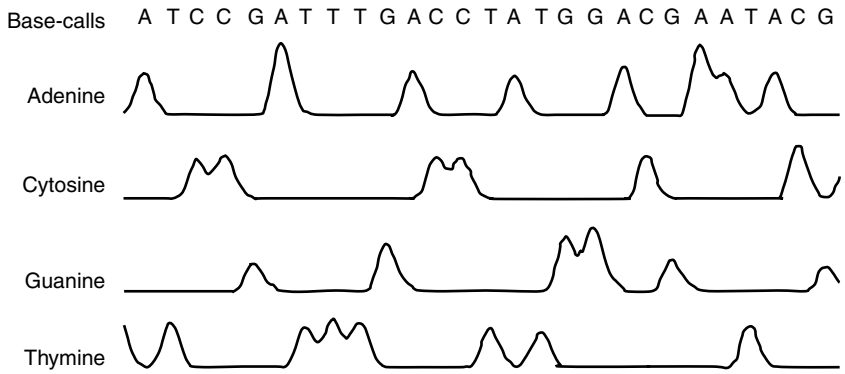

Fig. 4 A sequence chromatogram generated by an automatic sequencer and visualized as fluorescent intensity (*y*-axis) and electrophoretic mobility (*x*-axis).

programs available, including commercial software provided by manufacturers of automated DNA sequencers. The Phred program, developed by Phil Green at the University of Washington, is the most commonly used program today.

Phred base-calls in a four-step process. First, peak locations are predicted using Fourier methods. Prediction of peak location is necessary for regions where nucleotides are unreadable or ambiguous. In the next two steps, the program identifies observed peaks and matches them to the predicted peak locations. As observed peaks are matched to the predicted peak locations, the program is able to identify and resolve ambiguities in the sequence. Finally, any unambiguous observed peak that was not matched to a predicted peak is called and inserted into the sequence.

Owing to problems inherent in the sequencing reaction and in electrophoresis, sequence traces rarely yield a perfect sequence. Aberrant mobility of short sequences, unreacted sequencing reagents, DNA hairpin structures, and even simple diffusion can all produce regions of ambiguity in sequence traces. Because of these problems, Phred assigns an error probability to each base in the sequence. In calculating the error probability, Phred considers peak spacing, the ratio of the largest uncalled peak to the called peaks, and the peak resolution for the short sequence surrounding each nucleotide. Phred converts the error probabilities into ''quality values,'' which are 10 times the negative logarithm of the error probability. Thus, a quality value of 30 corresponds to an error probability of 1 in 1000. Higher Phred quality values are to be desired.

A second technical advance that facilitated the rate of genome sequencing is the advent of practical capillary electrophoresis. Originally, for each limited set of sequencing reactions, a separate polyacrylamide gel needed to be created for the electrophoresis step, and the slab gel had to be exposed to X-ray film to visualize the radioactively labeled DNA fragments. With fluorescent labels, the sequence can be read by a fluorescent detector during electrophoresis. In either case, the step of creating the slab gel was time consuming, and electrophoresis in a slab gel separates the sequencing fragments slowly. With capillary sequencers, the DNA fragments are fractionated by electrophoresis through a gel embedded in a capillary tube with an internal diameter

of 100 μ. Capillary sequencers require fewer reagents for the gel and completely eliminate the time-consuming process of manually preparing, loading, and editing the electrophoretic gel.

The addition of robotics to DNA sequencing processes provided a means to automate the more repetitive processes. When combined with fluorescent detection and capillary electrophoresis, highly automated sequencing devices such as the ABI PRISM 3730 or 3100 DNA Analyzers and the Amersham Pharmacia MegaBACE 4000 automated sequencing system can sequence hundreds of thousands of nucleotides everyday (Fig. 5). Special plates containing the results of sequence reactions are merely loaded into the machines. Robotics within the machine load each sample into a capillary, and detectors record the fluorescence as the fractionated sequencing fragments approach the end of the capillary.

Owing to limitations of the electrophoresis technique, approximately 500 to 1000 nucleotides can be reliably read from each template, even when using a capillary sequencer. To sequence even a small genome like the 0.5 Mb genome of *Mycoplasma genitalium*, the DNA molecule must be broken into small pieces that are able to be sequenced. The general strategy employed for recovering the complete sequence of a large DNA molecule is called *shotgun sequencing*. First proposed in the early 1980s, shotgun sequencing requires random fragmentation of the longer DNA molecule, cloning the fragments into a sequencing vector, and sequencing the fragments (Fig. 6). The sequence of the original DNA molecule is then assembled from the fragments using computational algorithms.

The first step in shotgun sequencing is the subcloning of the DNA sequencing target, also called *library construction*. In this step, the target DNA is broken into smaller pieces, which are then cloned into vectors that can be used in sequencing reactions. Any collection of clones that represent complete coverage of a larger piece of DNA is called a *library*. To create a sequence-ready shotgun library, the DNA of the target molecule is a fragment enzymatically by a partial digestion with a nuclease or restriction enzyme, or the DNA can be physically sheared, for example, by sonication. Physical shearing generally produces a more randomized sample of the target sequence and is more suitable for high throughput sequencing centers.

Two types of cloning vectors are available for shotgun sequencing, each with its advantages and disadvantages. The

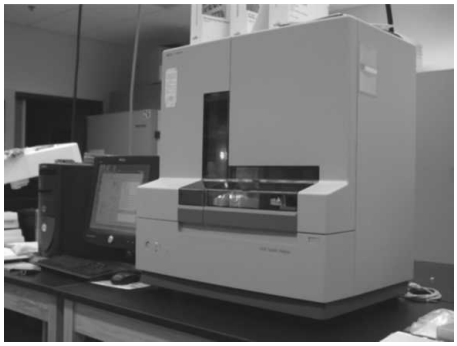

Fig. 5 A modern capillary sequencer, the ABI Prism 3100 Genetic Analyzer.

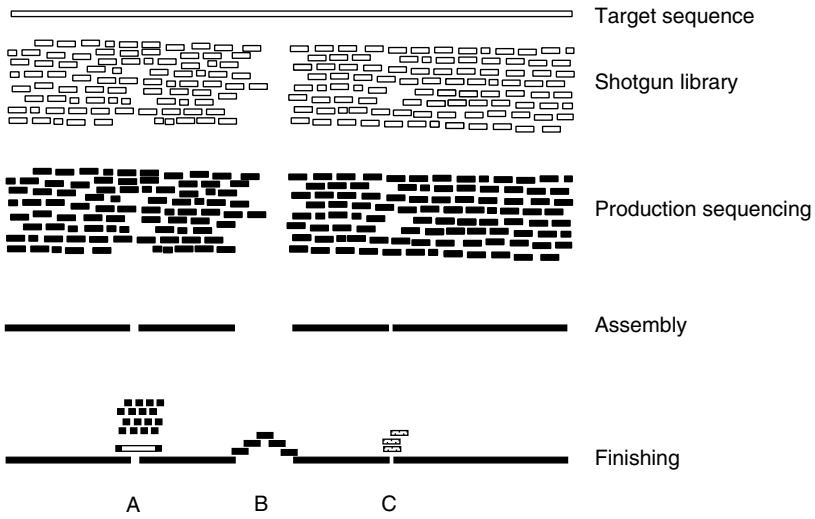

Fig. 6 In the shotgun-sequencing strategy, the target sequence is fragmented into random pieces, which are cloned in a sequencing vector to form the shotgun library. Production sequencing generates sequence data for the shotgun clones to at least a sixfold coverage. Computer programs assemble the shotgun reads into contiguous sequences. During finishing, various strategies are used to close the remaining gaps, including identification by end sequences and shotgun sequencing of a clone that spans the gap A, primer walking B, and alternative chemistry sequencing C.

first is bacteriophage M13, which naturally exists as single-stranded DNA. Since DNA sequencing templates must be single-stranded DNA, M13 naturally provides sequence-ready DNA templates. M13 clones exhibit a bias, in that repetitive sequences are poorly represented in M13 libraries. Alternatively, double-stranded plasmid clones can also serve as the vector for subcloning shotgun libraries. Plasmids do not exhibit the same cloning bias as M13 vectors, and thus represent the target DNA sequence more evenly. The disadvantage of plasmids is that they are double-stranded and therefore require additional steps to purify single-stranded DNA sequencing templates. A large genome-sequencing center will often use a combination of M13 and plasmid subclones for different sequencing needs.

Having created a suitable shotgun library, the next step is typically referred to as *production sequencing*, because it resembles the factory production typical of an assembly line. A random selection of shotgun clones is prepared and sequenced using the automated sequencing techniques discussed above. The number of clones necessary to reconstruct the original target sequence depends on the average length of sequence obtained from a single shotgun clone, the length of the target sequence, and the desired accuracy of the completed sequence. For production sequencing, genome-sequencing centers typically strive for a six- or eightfold coverage of the target sequence; that is, each nucleotide of the target is sequenced six (or eight) different times. This level of redundancy assures that most of the target sequence will be covered by the randomly

positioned shotgun clones, and whatever gaps or ambiguities remain after the shotgun sequencing can be quickly resolved.

After generating a sixfold redundant shotgun sequence, the sequence traces are then processed computationally. First, the traces are base-called using Phred or a comparable program. Second, the sequences are ''assembled'' into contiguous sequences called *contigs*. A contig is composed of two or more sequence reads that originate from an overlapping region of the target sequence. Contig assembly begins with an automated step, and concludes with a manual editing stage. The automated step is carried out by an assembler program such as Phrap, the TIGR Assembler, or CAP3. The assembler examines the sequence reads for regions of near identity (allowing for errors in the sequence read) and attempts to reconstruct the original target sequence. If the sequence reads were a perfect and redundant random representation of the target sequence, the assembler could theoretically reconstruct the entire target sequence from the shotgun sequence. In reality, variations in the quality of sequence reads, regions of the target with low shotgun representation, and repetitive sequences can result in assembly of many different contigs (depending on the size of the target sequence and the redundancy of the shotgun clones).

All assembly programs work in very similar ways. First, regions of overlap are identified by doing standard sequence comparisons between the sequence reads. Unlike a normal sequence comparison program, however, assemblers also consider the quality values of the sequence reads in calculating similarity scores between reads. From the overlap information, the assembler then reconstructs sequence contigs and some also calculate quality values of each nucleotide in the contig, based on the number of reads available at that position. To be certain that the contig comes only from the target sequence, sequence reads are typically filtered before assembly in order to remove contaminating DNA, such as vector sequence, that often appears at the 5′ end of a sequence read.

Having completed the automatic assembly, the sequence rarely resolves into a single contig of uniform quality. Reasons for obtaining multiple contigs include failure of the assembly program, cloning bias, regions that are difficult to sequence, and regions that were poorly represented in shotgun sequence reads by chance. To resolve these problems and to produce a single contig of uniform quality, manual inspection and editing of the contigs is necessary, together with additional sequencing reactions where appropriate. This manual phase is called either *gap closure* or more commonly *finishing*.

Finishing is aided by the use of a graphical contig editor such as Consed. For each assembly, Consed displays a list of the contigs and sequence reads. After selection of a contig, Consed displays the consensus sequence together with each sequence read that was assigned to that region by the assembler. The consensus sequence is displayed at the top of the assembly window, and the sequence reads appear in an alignment format just below the consensus (Fig. 7). Important features such as base quality are color-coded for easy identification of low-quality regions. Other windows in Consed display the actual chromatograms of any desired sequence reads.

The additional work necessary to close a gap in the sequence assembly depends on the cause of the gap. Regions of low shotgun representation can often be resolved by sequencing the opposite end

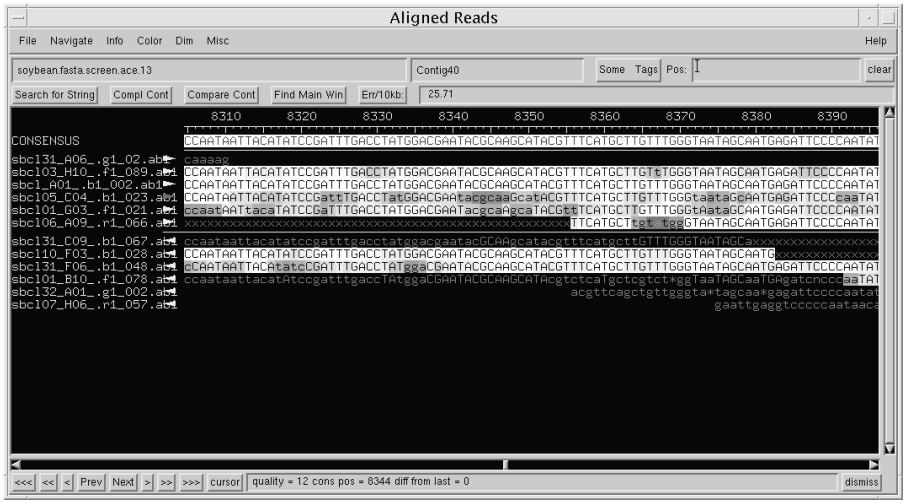

Fig. 7 A sequence assembly shown in a window of Consed. The consensus contig sequence is displayed at the top of the window, with individual sequence reads aligned and displayed beneath. The background color indicates the relative quality of base-calls. Uppercase letters with white backgrounds are of high quality; lowercase letters with black background are of poor quality. Nucleotides represented as *x* come from contaminating vector sequences, which have been removed prior to assembly.

of the clone insert for reads adjacent to the low-quality region. This will generate sequence reads for both ends of the clone insert and will usually provide sufficient sequence coverage to allow the gap to be closed. If the gap is caused by vector bias, it will be necessary to clone the missing region into a different vector. For example, as we discussed above, M13 does not effectively clone regions of repetitive DNA. Utilization of both M13 and plasmid clones can resolve problems caused by this cloning bias. In cases in which the assembly algorithm has failed to derive the correct consensus sequence, the statistical parameters of the assembly algorithm can be manipulated to generate the desired assembly. For example, assembly algorithms assemble regions with tandem repeats poorly. These errors are easily identified because of the abnormally large number of sequence reads assigned to a single region.

The most difficult class of problems encountered in finishing are regions that are intrinsically difficult to sequence, such as simple sequence repeats, homopolymeric regions, or regions with secondary structure. These types of gaps are easily identified because of the uniformity with which the quality drops off. In other types of gaps, the low quality may be observed in only a few of the shotgun reads, but in areas that are difficult to sequence, all shotgun reads will exhibit the same low quality at the same point in the sequence.

Resolution of sequence gaps requires a number of different strategies, each designed to deal with a particular sequencing problem. For example, specialized chemistry designed for simple sequence repeats can produce high-quality reads of repetitive regions. Larger repeats or secondary

structures could require a targeted subcloning strategy designed to break up the difficult region prior to sequencing. In another finishing strategy, called *primer walking*, sequencing primers are designed from the sequences at the boundaries of gaps. The sequencing reaction is then repeated, generating new sequence. This process of primer development and sequencing is repeated until the gap is closed.

After *finishing* has produced a single contig, the consensus sequence is validated in a number of ways. First, the length of the sequence is compared to the expected length of the target sequence. The expected length is typically measured by a restriction digest of the target sequence. Second, the length of the restriction fragments observed for the target sequence are compared to the length of the restriction fragments predicted for the consensus sequence. Whereas matching the length to the expected length confirms that a sequence of the correct size has been generated, matching the predicted and observed restriction fragment lengths ensures that the general order of the sequence assembly is good. This procedure can be repeated with multiple restriction enzymes to verify the assembly even further.

3 Sequencing Bacterial and Archaeal Genomes

As outlined in the previous section, the basic technique of shotgun sequencing is suitable for contiguous sequences of 10 Mb or less with few repeat sequences. For the small genomes of many bacteria and archaea, a straightforward shotgun strategy works well. The size and repetitive nature of eukaryotic genomes prevent the ready application of a shotgun-sequencing technique, necessitating specialized strategies for sequencing these genomes. Depending on the level of completion required, eukaryotic genomes are sequenced by a mapping strategy (for high-quality sequences) or by a whole-genome shotgun (WGS) strategy (for rough draft sequences), or by a hybrid of both. Strategies currently in development attempt to target the genes of large eukaryotic genomes by specialized cloning techniques. In this section, we will discuss the shotgun strategy used to generate the first bacterial genome sequence, *Haemophilus influenzae*. The following section will focus on strategies used in eukaryotic genome sequencing.

The first organismal genome completely sequenced by the shotgun method was that of *H. influenzae*, sequenced by a team from the Institute for Genomic Research (TIGR) and published in 1995. As a bacterial genome, the repetitive DNA content was much lower than most eukaryotes, and the size of the complete chromosome was only 1.8 million nucleotides. Despite being the first organismal genome, the issues considered and strategies employed in sequencing are still representative of modern genome projects.

Because the success of the shotgun method depends on a random selection of sequence templates, the TIGR team expended much care on template library construction. Two types of libraries were made for the *H. influenzae* project: a short-insert (1.6–2 kb) plasmid library and two long-insert (15–20 kb) λ phage libraries. The plasmid library was used as the primary sequencing template, while the λ libraries were reserved for finishing and validation (we will discuss the utilization of the λ libraries below). For all libraries, the genomic DNA was

mechanically sheared rather than digested by restriction enzymes. As mentioned previously, shearing the source DNA ensures a more random library sample than restriction digest.

On the basis of simple statistical calculations, we know that the probability that a nucleotide will be unsequenced in a shotgun-sequencing project is $P_o = e^{-m}$, where m is the genome coverage. Sequencing random clones sufficient to cover the genome five times (fivefold coverage) results in a probability of 0.0067 that a nucleotide will be unsequenced. For the 1.8 million-nucleotide *H. influenzae* genome, a fivefold shotgun coverage should result in approximately 12 000 unsequenced nucleotides, distributed randomly throughout the genome in sequence gaps between the contigs.

Given an average high-quality read-length of 460 nucleotides (the limits of the sequencing technology at that time), approximately 19 000 sequence reads would be necessary to cover the *H. influenzae* five times. The TIGR team sequenced 19 687 short-insert templates using dye-primer sequencing chemistry (*forward reads*). To supplement these reads and to provide contig assembly information, 9297 templates were re-sequenced at the opposite end of the insert (known as *reverse reads*), also using dye-primer chemistry. The result is a pair of 460-nucleotide sequence reads that are known to be 700–1100 nucleotides apart, a significant advantage during finishing.

Automatic assembly of forward and reverse reads yielded 210 contigs. Because the parameters used in assembly are optimized for general use, local variations can occur due to differences in repeat- or GC-content. As a result, manual inspection of potential overlaps resulted in a reduction to only 140 contigs, which could not be further combined without additional sequencing reactions. The remaining gaps could be categorized into two types depending on the orientation of paired sequence reads. If the forward reads at the end of one contig matched the corresponding reverse reads from the same template at the end of a second contig, the TIGR team called the gap a *sequence gap*. Because they are spanned by a single, small-insert plasmid, sequence gaps are known to be small (less than 1500 nucleotides), and known templates (the plasmid inserts spanning the gaps) are available for immediate, additional sequencing. For the *H. influenzae* genome, 98 gaps were sequence gaps.

The second type of gap occurred when forward/reverse reads of the same template did not span the gap. The TIGR team labeled these gaps *physical gaps*, because a clone insert that spanned the gap was not immediately available. Additional strategies were devised to identify and prepare suitable sequencing templates that spanned the physical gaps. For two gaps, protein sequences could be used to orient the adjacent contigs. This was possible because the gap occurred within a protein-coding gene, the 5′ end of which was sequenced on one contig and the 3′ end on another. By comparing the contig sequences to known protein sequences, these overlaps could be detected and PCR used to generate suitable sequencing templates.

The majority of the gaps were closed using one of two strategies. First, DNA fingerprinting and hybridization to oligonucleotides prepared from the ends of contigs revealed possible overlapping DNA segments, from which templates could be prepared. For example, if oligonucleotide probes prepared from the ends of two

contigs hybridized to the same restriction fragment of the genomic DNA, it is likely that the hybridizing fragment contains the sequence spanning the gap between the two contigs. The other successful gap closure method was the paired forward/reverse sequences from the λ libraries. Small gaps are more likely to be spanned by the large inserts (15–20 kb) of the λ libraries than the small inserts (~2 kb) of the plasmid library. The remaining physical gaps were closed by simple combinatorial PCR, systematically using oligonucleotide primers from each possible contig pair.

These strategies resulted in a single contig with a consensus sequence of 1 830 137 nucleotides. The assembly of the consensus sequence was validated using additional λ library forward/reverse sequence reads and restriction fragments and restriction site locations. Since the λ library has a known insert size of 15–20 kb, paired reads that deviate significantly from that distance would indicate a misassembly. Sizes of restriction fragments generated by three different enzymes could also be matched to the predicted sizes of the consensus sequence. Restriction site locations from restriction mapping could also be matched to the restriction sites found on the consensus sequence. For all of these validations, the *H. influenzae* consensus sequence matched the observed characteristics of the genome.

Despite being the very first bacterial genome to be sequenced by the shotgun method, much of the techniques and strategies developed are the same as those used today for bacterial and archaeal genome projects. Library construction remains an important step to assure a random coverage of the genome. Sequencing both ends of the inserts and using different sequencing chemistries are both common strategies for gap closure and finishing. The major difference between a modern genome project and the *H. influenzae* project is the rate. Facilitated by capillary sequencers and more powerful computers for assembly and finishing, a bacterial genome of the same size as *H. influenzae* can be completed in a fraction of the time and at a fraction of the cost.

4 Sequencing Eukaryotic Genomes

Eukaryotic genomes differ from bacterial and archaeal genomes in several important ways that make genome-sequencing projects more complex. Although several bacteria and archaea are known to have multiple chromosomes or *megaplasmids*, a typical prokaryotic genome is a single, circular chromosome. In contrast, eukaryotic genomes are divided into several (sometimes many) linear chromosomes. Eukaryotic genomes are also much larger, on average: the largest bacterial genome sequenced to date is the 9 Mb chromosome from *Bradyrhizobium japonicum*. At 3200 Mb, the human genome is approximately 355 times larger (see also Fig. 8). The size and multiple chromosomes alone would challenge the assembly algorithms and finishers, but the sequence of eukaryotic genomes also contain a high repeat content, rendering cloning, sequencing, and assembly of particular regions extremely difficult.

Because of these limitations, extra presequencing strategies must be utilized to make the genome amenable to sequencing, and the definition of ''finished genome'' is often project-specific. The most common strategy employed for eukaryotic genome sequencing is a ''map-then-sequence'' approach that seeks to

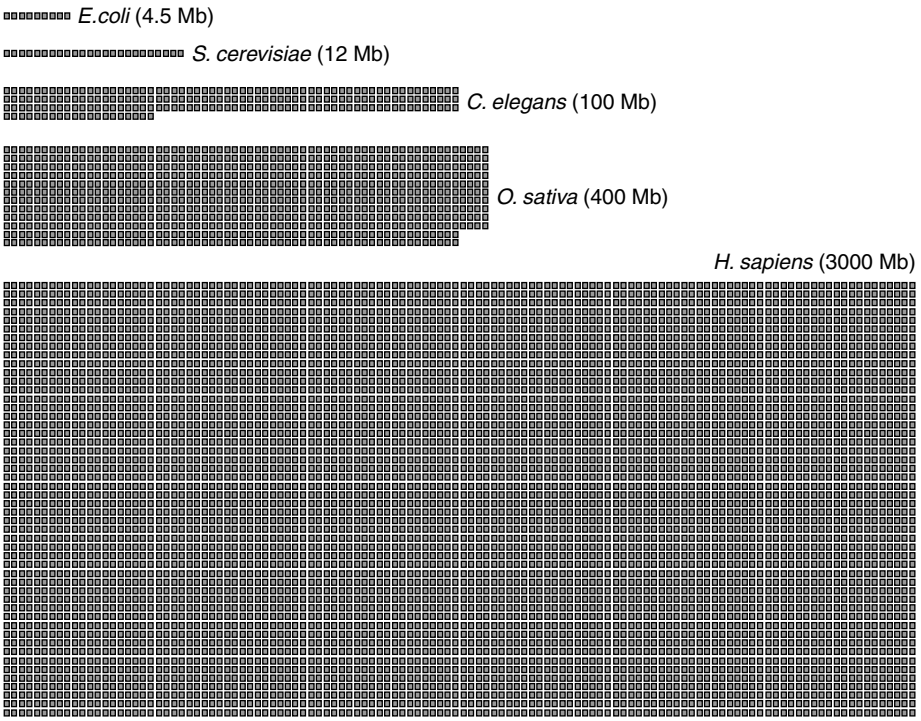

Fig. 8 Relative sizes of sequenced genomes. Each square represents 500 000 nucleotides, approximately the size of the complete *M. genitalium* genome. Genomes shown represent the K12 strain of *E. coli*, baker's yeast *S. cerevisiae*, the nematode *C. elegans*, rice *O. sativa*, and the human genome *H. sapiens*.

obtain a physical map of the genome prior to the shotgun-sequencing phase. The physical map is composed of ordered, overlapping large-insert clones anchored to markers in the genome, identified by genetic or cytogenetic mapping. On the basis of the order and orientation of the map, individual clones are selected and subjected to the standard shotgun sequencing and finishing, as described above (Fig. 9). There are several advantages to this strategy, including an overall reduction in the number of repeats that need to be resolved during any particular finishing phase and the identification of problem regions before sequencing even begins.

Ideally, the physical map and finished genome sequence should cover the entire genome, but this level of accuracy is rarely achieved. Regions of concentrated repeats, such as telomeres and centromeres, do not clone well and are extremely difficult to sequence. Regions of high repeat content are called *heterochromatin*. Euchromatin has a much lower repeat concentration and is believed to contain the majority of the genes. As a result, most eukaryotic sequencing projects aim to completely sequence the euchromatic regions of the genome. For example, approximately one-third of the fruitfly (*Drosophila melanogaster*) genome was heterochromatic and consequently not sequenced. Even when dealing with just

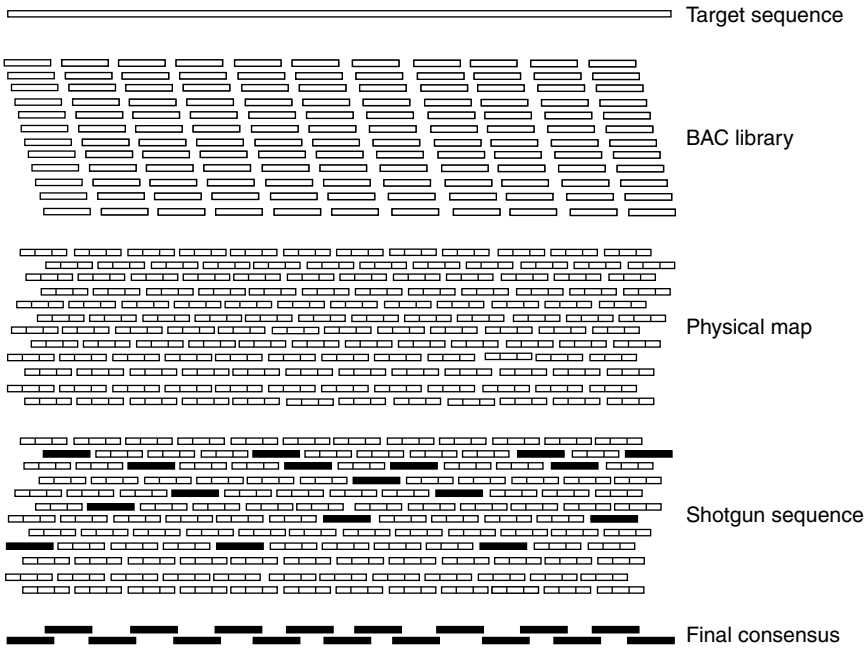

Fig. 9 The map-then-sequence strategy used for large, eukaryotic genomes. The target sequence is fragmented by partial restriction digest and cloned into a large-insert BAC library. The BAC inserts are fingerprinted and overlaps detected to generate a physical map. On the basis of the physical map, clones are selected for shotgun sequencing (see Fig. 6), and the final consensus consists of a series of overlapping clones.

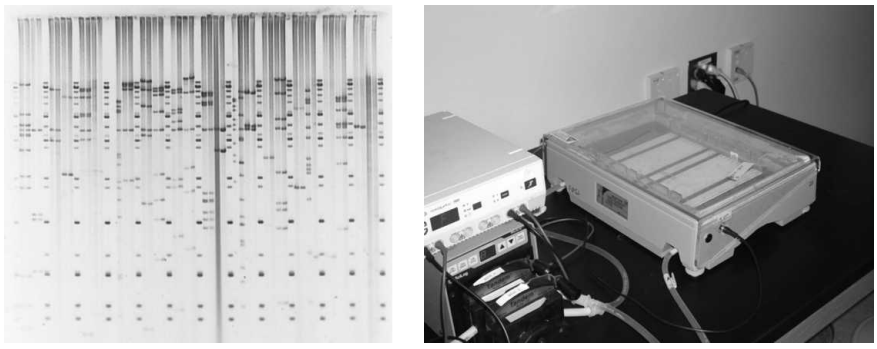
euchromatin, small regions that are difficult to sequence can still occur, and most eukaryotic genome projects allow for a certain number of gaps in the ''finished'' product, provided the gap length is known. The public Human Genome Project allows an unspecified number of gaps, as long as their length is less than 150 kb.

Because physical mapping is beyond the scope of this article, we will here provide only a cursory overview of the map and sequence strategy. A physical map begins with the construction of large-insert libraries. Currently, the vector of choice for mapping is the bacterial artificial chromosome (BAC). BACs can hold approximately 100–300 kb of insert and are not prone to recombination. Unlike shotgun libraries, the source DNA for a BAC library is typically fragmented by partial restriction digest. Protocols for BAC cloning randomly sheared DNA are still in development. Because of the inherent biases introduced by partial restriction digests, multiple libraries constructed with different restriction enzymes are often necessary to get complete, random coverage of the genome.

After the construction of the genomic library, BAC inserts are ordered and aligned by ''fingerprint'' analysis. Each clone is completely digested with the same restriction enzyme, and the fragments are fractionated and viewed by agarose gel electrophoresis (Fig. 10). A new technology called *high information*



(a) (b)

Fig. 10 (a) A fingerprint gel generated from a large-insert BAC library of rice (b) and the electrophoresis apparatus used for fingerprinting.

content fingerprinting (HICF) utilizes up to five different restriction enzymes followed by dye labeling and electrophoresis on a DNA capillary sequencer rather than a standard agarose gel. HICF reduces labor, increases automation and the number of fragments per BAC, and allows automatic measurement of fragment mobility from chromatograms. Owing to the increased fragment number, more robust contigs can be generated from the fingerprint data.

The relative mobilities of each clone's restriction fragments are loaded into a computer program (such as FPC) that determines overlapping regions between clones based on shared fragment mobilities. The result is a set of physical map contigs (Fig. 11). Because restriction fingerprints provide less data than actual sequencing, the assembly of physical map contigs is less precise than sequence contigs and consequently requires a deeper coverage of the genome. Many physical maps cover the genome 10 to 15 times. As with shotgun sequencing, the coverage is uneven, and many difficult-to-clone regions of the genome may be missing from the physical map contigs. Closure of gaps in physical maps takes place through both computational and additional laboratory experiments, using some strategies analogous to gap closure in sequence finishing.

The goal of the physical mapping effort is to produce a set of minimally overlapping clones that cover the entire euchromatic portion of the genome, also called a *sequence-ready* map. Because the coverage can be uneven, the physical map must be ''anchored'' by hybridization with marker sequences of a known, unique genomic position. These markers can be identified by a number of mapping methods, including traditional genetic mapping. Once the physical map is anchored, any remaining gaps in the euchromatin coverage can be identified, and strategies to fill those gaps can be devised and implemented.

As an aid to the creation of the sequence-ready map, the ends of the BAC clone inserts can be sequenced. Although some of these ''BAC-end sequences'' or ''sequence-tagged connectors'' (STCs) will undoubtedly come from repetitive sequence, many will be unique sequences that represent the ends of only one clone insert. STCs of clones bordering gaps in the physical map can be used to generate novel probes to identify clones and possibly contigs that span the gap. During the

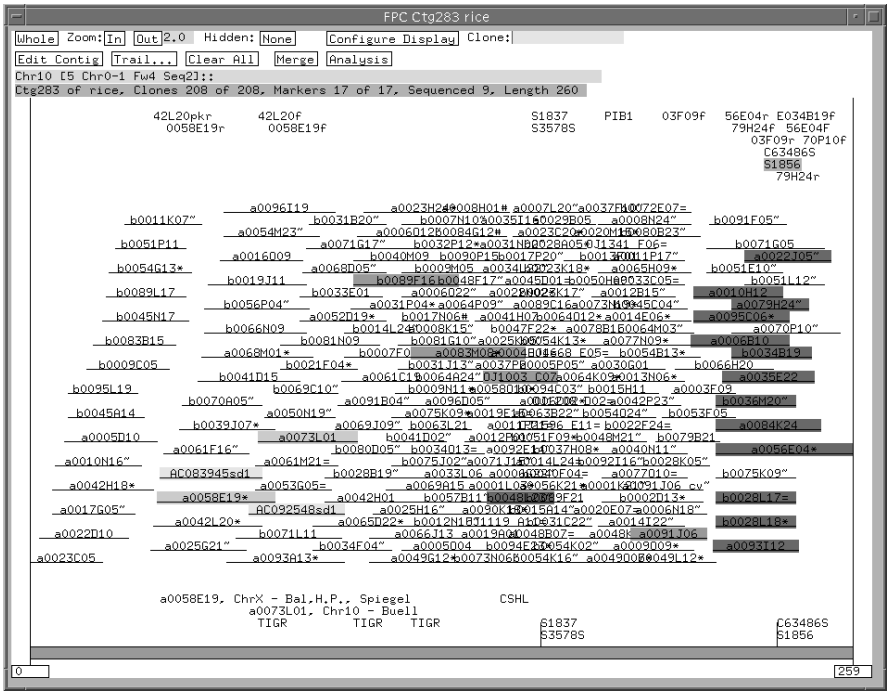


Fig. 11 A physical map contig from the rice genome, as displayed by the physical mapping software FPC.

sequencing phase, STCs can be used to choose the next minimally overlapping clone with a great deal of precision. STCs can also be a valuable dataset in their own right by providing a preliminary survey of the contents of a eukaryotic genome.

After (or even during) construction of the physical map, sequencing can commence using the standard shotgun method. A sequence-ready clone is chosen, shotgun libraries are prepared, and the clone is sequenced. Additional clones are selected and sequenced with minimal overlap with the existing sequence. Finishing is limited to the regions that do not overlap with an existing, finished sequence.

With a physical map, another advantage becomes immediately apparent. Unlike a pure shotgun approach for small genomes, the sequencing of a mapped genome can be divided between more than one sequencing center. The genome can be divided into regions or even whole chromosomes, and sequencing can take place in many different labs simultaneously. Additionally, even at a single sequencing center, sequencing can commence at different positions in the genome. As new sequence-ready clones are identified by physical mapping, shotgun sequencing and finishing can commence on other clones. Thus, the mapping and sequencing at a single lab can proceed simultaneously.

The map-then-sequence strategy has been successfully applied to several prominent eukaryotic genome projects. Genome sequences of the nematode *Caenorhabditis elegans* and the plant *Arabidopsis thaliana* were both completed in this way, and the public Human Genome Project also

used this method. The alternative strategy is the whole-genome shotgun (WGS) or a mixture of mapping and WGS. WGS sequences are rarely finished to the same quality as a mapped-and-sequenced genome, but for certain genome projects, WGS provides a reasonable and affordable alternative to a completed sequence. Because of the unfinished quality of WGS sequences, they are often referred to as *draft sequences*.

Though the vast majority of genome sequence is obtained during the shotgun-sequencing phase, the majority of effort (and money) is invested in the finishing phase. With the complete human genome sequence, finished genome sequences from other vertebrates may be an unnecessary expense for comparatively little information. Because genomes of mammals and vertebrates have conserved gene content and order, the human genome sequence can serve as a reference template for other genome sequences. A WGS project could generate four- or fivefold coverage of the genome and still theoretically achieve 98% coverage of the euchromatic region of the genome. A WGS for a vertebrate would produce a very large number of sequence contigs that could be ordered by reference to the human genome.

As with a standard shotgun-sequencing project, a eukaryotic WGS begins with careful construction of genomic clone libraries. Celera's attempt to sequence the human genome by WGS showed that multiple clone libraries with differing insert sizes are essential to the assembly of sequence contigs. For each library, both ends of the clone inserts must be sequenced to provide pairs of sequences of a known distance apart on the chromosome. Paired-end sequences are necessary to order and orient sequence contigs into "*scaffolds*." Finally, the actual assembly of eukaryotic WGS sequence reads usually proceeds in a multistep process, even with advanced computational hardware. Typically, the repeat sequences will be masked in the early assembly steps to prevent misassembly due to highly conserved repetitive sequences. Once contigs and scaffolds of unique sequences have been assembled, the repeat sequences can be added back to the assembly with the unique sequences acting as an assembly framework.

A third application of WGS is to use a mixed approach, with elements of both map-then-sequence and WGS. For example, a low-coverage WGS can be generated rapidly at a large genome-sequencing center while finishing could be completed on a clone-by-clone basis at smaller sequencing centers. This hybrid approach was used for the *Drosophila* genome project. Celera provided a nearly 15-fold shotgun coverage of the *Drosophila* genome, and finishing was completed in a number of publicly funded laboratories.

Despite the advantages of WGS for some eukaryotes, the drawbacks are also significant. Experience with the rice genome has shown that contigs produced by WGS may be a poor substrate for *ab initio* gene prediction (see below). In a detailed analysis of the complete sequence of rice chromosome 10, researchers predicted twice as many genes as had been predicted by previous WGS sequencing efforts of the same chromosome. Additionally, genes predicted from the WGS contigs were on average one-third shorter than genes predicted from the finished sequence.

Several new techniques have been proposed for specifically targeting gene-rich sequences during the initial library construction, prior to shotgun sequencing. In one method, methylated DNA is eliminated prior to library construction. In

eukaryotic genomes, transposons are often methylated at CpG dinucleotides as a means of downregulating their transcription. By excluding methylated DNA from library construction, only unmethylated genes should be included in the library. The primary drawback of this method is that most organisms use methylation as a means of transcriptional control of cellular genes as well as transposons. The second method of gene-targeted cloning, called *cot-based cloning and sequencing* (CBCS), relies on the fact that repetitive DNA reanneals more quickly than unique DNA after denaturation. By isolating the DNA that reanneals the slowest, nonrepetitive DNA can be cloned without eliminating methylated genes. Both these techniques are still in the development phase and have not yet been widely applied to genome sequencing.

5 Interpreting the Sequence

Once the genome sequence has been completed to a previously defined set of quality standards, the biologically important features of the sequence can be identified in a process called *annotation*. Biologically important features identified in a typical genome project include genes and transposable elements. For bacterial or archaeal genomes, gene identification is relatively straightforward, while gene identification in eukaryotic genomes is much more difficult due to the presence of introns. Three basic methods are used for protein-coding gene identification: *ab initio* gene prediction, sequence similarity searches, and expressed-sequence tag (EST) sequencing. All genome projects use both gene prediction and homology searching, while EST sequencing is primarily a technique for eukaryotic gene identification.

The goal of *ab initio* gene prediction is to correctly identify the start and stop codons (and intron/exon boundaries, if relevant) of a gene given only the DNA sequence and statistical parameters derived from known genes. For the simple structure of a bacterial or archaeal genome, genes can be identified from open reading frames that match a known set of codon preferences. Glimmer is a popular program for prokaryotic gene prediction. Statistical parameters considered for eukaryotic genes can include codon preferences, frequencies of longer combinations of codons, and attributes of intron/exon boundaries. These statistical parameters are derived from analyses of a large number of experimentally identified and sequenced genes. Because eukaryotic gene-prediction algorithms must correctly identify all possible exons, some of which can be very short, gene prediction in eukaryotic DNA is much less accurate than in prokaryotic DNA. Genscan and FGenesH are commonly used eukaryotic gene-prediction programs.

Genes can also be identified by their similarity to known sequences. Programs such as BLAST or FASTA compare a query sequence to a database of sequences. For each sequence in the database, a similarity score is calculated, and the statistical significance of each similarity score can be estimated with a high degree of accuracy. If the query sequence matches a sequence in the database with a statistically significant similarity score, we can infer with confidence that the sequences are related either through a common biochemical or physiological function. Because the statistical properties of sequence similarity scores are well understood, sequence similarity searching is the most

reliable computational method of identifying protein-coding genes, RNA genes, pseudogenes, and transposable elements. Because sequence similarity programs do not identify start and stop codons or intron/exon boundaries, additional manual editing is necessary to derive a gene prediction from the significant similarity to a known sequence.

Because eukaryotic gene-prediction algorithms do not produce completely reliable results, experimental evidence is often sought to supplement computational gene identification efforts. The most common experimental method of gene identification is to isolate messenger RNAs, clone their cDNAs into a sequencing vector, and generate a single sequence read from each clone. Although the single read is insufficient to sequence the entire cDNA to high quality, it is generally enough to generate 500–700 nucleotides of the cDNA. This sequence information serves as a tag that can mark the location of a gene in genomic sequence, hence the name expressed-sequence tag. EST sequences are collected into databases, which are then compared to genomic sequence using sequence comparison programs (BLAST and FASTA). Gene identification by EST is limited by the isolation and preparation of pure mRNA sequences, because rRNA and other stable RNA can contaminate the cDNA library. Furthermore, any one tissue only transcribes a fraction of potential genes at any one time. cDNA libraries should be constructed from multiple tissues at multiple growth stages.

A typical eukaryotic genome project will utilize every gene identification method during annotation. Several different *ab initio* gene-prediction programs will be run on the genomic sequence. Additionally, sequence similarity searches will be performed on several different databases, including previously characterized protein sequences, known transposable elements, and ESTs from the target organism (and closely related species where available). The results of these computational analyses are then manually edited into a final annotation by a trained genome researcher. The annotation and the sequence can be deposited in one of the public DNA sequence databases, such as GenBank.

6 Summary and Principles

As consumers of genomic information, the majority of biologists are not directly involved in the generation of genome sequence data. Consequently, it is important for biologists to understand how genome sequence data is obtained in order to appreciate the advantages and limitations of using complete genomes. As we have explained, there is no single definition of ''complete genome'' to which all genome projects conform. Different levels of completion provide their own strengths and weaknesses. Sequences completed to the quality of most bacterial genomes and early eukaryotic genomes (yeast, *Caenorhabditis elegans*, *Arabidopsis*) give excellent insight into both the content and organization of the genome. For eukaryotes, such high-quality genome sequences require significant investment of time and funding. Draft sequences created by WGS are excellent for comparative genomics with close relatives (especially if the close relative has a high-quality completed sequence) and can provide insight into gene content. Draft sequences are probably unsuitable for comparative genomics with distantly related organisms and may not be adequate for *ab initio* gene prediction.

It is helpful to remember that the completed genome sequence is experimental data and subject to experimental error. Even high-quality, finished genome sequences will have errors. Most genomic sequence that is subject to finishing is completed to an accuracy of 1 error in 10 000 nucleotides. With three billion nucleotides, we should expect 300 000 single-nucleotide errors in the human genome sequence. For most researchers, this level of error will hardly ever be noticeable, but occasionally researchers may stumble across one of these errors.

Finally, researchers should also keep in mind that efforts to annotate genomic sequence, and in particular to identify protein-coding genes, are subject to much higher and less quantifiable error rates than actually obtaining the sequence itself. For important research projects on particular genes or gene families, predicted genes should be subjected to experimental verification, based on the evidence used to predict the gene. Genes predicted from a combination of EST similarity, *ab initio* predictions, and significant similarity to a closely related protein sequence will require less verification than those predicted from *ab initio* gene-prediction software alone.

Presently, genome technology and sequencing continues to grow at an amazing rate. Many of the strategies and limitations discussed in this article could be resolved at some time in the future. As genomics continues to grow, our understanding of the chemical basis of life will also grow, providing new platforms and methods for understanding disease, inheritance, and evolution. The benefits of investing in genome sequencing will continue to be discovered for years to come.

Keywords

Anomers
The two isomeric structures, formed because the aldose C-1 atom becomes asymmetric in making the sugar chains, are called the α- and the β-anomers.

Fc Receptor
A cell-surface receptor that binds the hinge region of immunoglobulin G.

Furanose
The isomeric ring structure formed by four carbons and one oxygen atom of aldoses and ketoses.

Glycoconjugates
The generic name of carbohydrates that are linked to various biomolecules. They can be classified into glycoproteins, glycolipids, and proteoglycans.

Glycohormones
Peptide hormones containing sugar chains.

Glycon and Aglycon
Glycosidases, which cleave the sugar chains, have two kinds of specificity: one for glycon and one for aglycon. Glycon specificity is directed to the sugar moiety released from the portion of a sugar chain containing a reducing terminal, and its anomeric configuration. The aglycon specificity is directed to the structure of the portion to which the released sugars are linked. This specificity varies by enzymes. For example, diplococcal β-galactosidase cleaves the Galβ1$\rightarrow$4GlcNAc linkage but not the Galβ1$\rightarrow$3GlcNAc and the Galβ1$\rightarrow$6GlcNAc linkages. In contrast, the enzyme from *Streptococcus* 6646K hydrolyzes all three linkages.

Lectin
The general name for proteins other than antibodies that bind specifically to particular sugar chain structures.

Oligosaccharide Alcohols
Oligosaccharides, the reducing termini of which are converted to alditols.

Protein C
A serine protease zymogen; becomes a potent inhibitor of blood coagulation upon activation by thrombin.

Pyranose
The isomeric ring structure formed by five carbons and one oxygen atom of aldoses and ketoses.

Many proteins produced by multicellular organisms contain covalently linked sugar chains and are called *glycoproteins*. Because of the difficulties associated with the structural study of the sugar chains of glycoproteins, however, the functional aspects of the sugar moieties of glycoproteins were ignored during the long history of protein research.

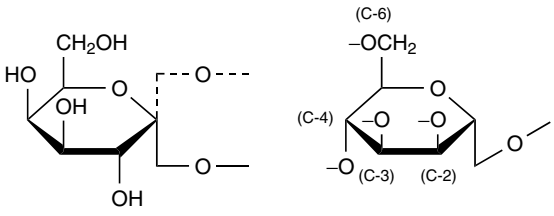
In addition to the structural multiplicity, another factor makes the structural study of the sugar chains of glycoproteins difficult. Many glycoproteins contain more than one sugar chain in one molecule. Even in the case of a glycoprotein with only one sugar chain, there is widespread microheterogeneity of sugar chain structure because the absence of a template in the biosynthetic machinery of sugar chains makes possible the formation of incomplete chains. Therefore, each sugar chain must be separated before it can be subjected to structural study.

Interest in glycoconjugate research was stimulated early in the 1960s by elucidation of the antigenic determinants of human blood types and the molecular basis of antigenic conversion of bacteria. This research area has further attracted the interest of biologists, because many studies on cell biology have suggested the possibility that the sugar chains of glycoproteins and glycolipids play an important role as signals of cell-to-cell recognition, which are crucial in multicellular organisms.

Development of gene technology in recent years has also accelerated the functional study of glycoprotein sugar chains. This technology has opened a way to obtaining substantial amounts of bioactive proteins, which are useful but occur in small amounts in the animal body. However, many proteins produced by animal cells occur as glycoproteins. Since many nonglycosylated recombinant proteins, obtained by using bacterial hosts, do not express the expected biological activities, importance of the study of their sugar moieties has been noticed. ''Glycobiology'' is a scientific field established on the basis of the possibility of elucidating the biological information in the sugar chains of glycoconjugates and using these data to increase our knowledge of biology.

1 Introduction

In contrast to nucleic acids and proteins, sugar chains of many different structures can be formed by using a small number of monosaccharide units. Let us consider the smallest unit of chains: A–B. In the case of nucleic acids, only one structure is made by assigning adenylic acid to A and guanylic acid to B. In the case of protein also, only one structure is made when A and B are assigned to valine and serine respectively. In the case of sugar chains, however, many isomeric structures are formed. Suppose that A and B are assigned to galactose and mannose respectively. As shown in Fig. 1, galactose can be linked at the four hydroxyl groups of mannose: C-2, C-3, C-4, and C-6. Accordingly, four isomeric structures can be formed. By virtue of the ability of the galactose residue to take two anomeric configurations, α (solid line in Fig. 1) and β (dotted line in Fig. 1), the number of possible isomeric structures becomes eight. Furthermore, galactose residues can occur



(a) Galactose (b) Mannose

Fig. 1 Construction of sugar chains.

in the furanose form as well as in the pyranose form shown in Fig. 1. Thus, 16 isomeric structures are possible for the disaccharide Gal→Man. When the number of units increases (to three, four, etc.), only one structure can be formed by assigning a particular unit at each position in the case of nucleic acids and proteins, because they are linear constructs. In contrast, the number of isomeric sugar chains increases by geometrical progression, because branching can be formed in sugar chains larger than a disaccharide. This means that sugar chains, but not nucleic acids and proteins, have the following characteristic feature: they can form multiple structures with a small number of units.

2 Principles of Studying the Sugar Chains of Glycoconjugates

2.1 Release of Sugar Chains of Glycoconjugates as Oligosaccharides

As already described, each sugar chain of a glycoconjugate must be isolated for structural study. The sugar chains of glycoproteins can be classified into two groups, *O*-linked and *N*-linked. An *O*-linked or mucin-type sugar chain contains at its reducing terminus an *N*-acetylgalactosamine residue that is linked to the hydroxyl group of either a serine or a threonine residue in a polypeptide chain. Such sugar chains can be released as oligosaccharide alcohols by heating the glycoprotein at 48 °C in a solution of 1 M $NaBH_4$ and 0.05 N NaOH for 16 h. The use of hydrazinolysis to remove acyl groups from the *N*-acetylaminosugar residues of oligosaccharide alcohols, followed by re-*N*-acetylation with ^{14}C- or ^{3}H-labeled acetic anhydride, will produce isotope-labeled oligosaccharide alcohols, which are useful for fractionation and structural analyses.

The other group of sugar chains of glycoproteins, the *N*-linked or asparagine-linked sugar chains, are linked to the amide group of an asparagine polypeptide residue; each one contains an *N*-acetylglucosamine residue at its reducing terminus. These sugar chains are quantitatively released as oligosaccharides by heating thoroughly dried glycoproteins in anhydrous hydrazine at 80 to 100 °C for 8 to 10 h. Although some of the acetyl groups of the *N*-acetylaminosugars of oligosaccharides are removed by hydrazinolysis, they can be recovered by *N*-acetylation of the oligosaccharide fraction. The oligosaccharides can be converted quantitatively to ^{3}H-labeled oligosaccharide alcohols by reduction with [^{3}H]$NaBH_4$. Although the mechanism is not known, it was reported that *O*-linked sugar chains are cleaved by milder hydrazinolysis (60 °C for 5 h). This treatment can be effectively used for converting *O*-linked sugar chains to oligosaccharides with reducing terminal.

N-Glycanases (glycopeptidases) from several biological sources are commercially available. These enzymes hydrolytically cleave the GlcNAc→Asn linkages of glycoproteins and leave aspartic acid residues on the polypeptide portion. The glycosylamine residues of the released oligosaccharides are spontaneously hydrolyzed into oligosaccharides and ammonia. With this catalytic action, the enzymes release all *N*-linked sugar chains of glycoproteins without destroying the polypeptide moieties. However, one must take care for the limits of application of these enzymes, because they can have substrate specificities including the steric hindrance of the polypeptide portion.

Several endo-β-*N*-acetylglucosaminidases (hereafter referred to as *endos*), which act on *N*-linked sugar chains, were reported. These enzymes hydrolytically cleave the *N*,*N*′-diacetylchitobiose moieties located at the reducing termini of *N*-linked sugar chains. Accordingly, the enzymes release most of the sugar chains of glycoproteins intact by leaving either the *N*-acetylglucosamine residue or the Fucα1→6GlcNAc group on the polypeptides. Some of these enzymes are now commercially available and each one has a unique substrate specificity (Table 1). Endo D requires Manα1→3Manβ1→4GlcNAc for its glycon specificity. The α-mannosyl residue of the trisaccharide group is the most important and should not be linked by other sugars except at its C-4 position. Endo H requires for its specific glycon a tetrasaccharide structure: Manα1→3Manα1→6Manβ1→4GlcNAc. Again, the most important sugar residue is the α-mannosyl residue at the nonreducing terminal. Addition of sugars at the hydroxyl group except for the C-2 position of this residue will make the oligosaccharide resistant to the enzyme action. Endo C_{II} requires for its specific glycon a branched pentasaccharide: Manα1→3Manα1→6(Manα1→3)Manβ1→4GlcNAc. The two terminal α-mannosyl residues must be either nonsubstituted or replaced by other sugars only at their C-2 positions. These enzymes have rather broad aglycon specificities, since they cleave the sugar chains linked to *N*-acetylglucosamine, the Fucα1→6GlcNAc, the GlcNAc→Asn (peptides), and the Fucα1→6GlcNAc→Asn (peptides) groups. The enzymes except for endo H can also cleave the sugar chains linked to *N*-acetylglucosaminitol and the Fucα1→6*N*-acetylglucosaminitol groups, but the rate of hydrolysis is much lower than others. Recently, another endo-β-*N*-acetylglucosaminidase called *endo M*, which can cleave most of the *N*-linked sugar chains, were found in the culture medium of *Mucor hiemalis*. This enzyme may be useful for the future development of glycotechnology because it also has transglycosylation activity. An interesting evidence is that the enzyme can transglycosylate *N*-linked sugar chains to the GlcNAcβ1-Gln (peptides) groups as well as the GlcNAcβ1-Asn (peptides) groups.

Several other endoglycosidases shown in Table 1 were also found and have been used for the study of sugar chains. Endo-α-*N*-acetylgalactosaminidase hydrolytically cleaves the GalNAcα1→Ser (or Thr) linkage of the Galβ1→3GalNAcα1→Ser (or Thr) peptides and is commercially available by the name of *O*-glycanase. Endo-β-galactosidases with different substrate specificities have been obtained from various bacteria. The endo-β-galactosidase from *Streptococcus pneumoniae* releases the GalNAcα1→3(Fucα1→2)Gal and the Galα1→3(Fucα1→2)Gal groups from

Tab. 1 Structural requirements of endoglycosidases.

Enzyme Name	***Substrate Structure***

Type II (see Sect. 5) blood group A and B active sugar chains respectively. The enzyme has been successfully used to characterize the blood group substances.

Endo-β-galactosidases from *Escherichia freundii* and from *Bacteroides fragilis* hydrolytically cleave the β-galactosidic linkages in the $(Gal\beta1\rightarrow4GlcNAc\beta1\rightarrow3)_n$

groups (*N*-acetyllactosaminoglycan) included in the sugar chains of glycoconjugates. Although the enzyme from *E. freundii* cleaves most of the β-galactosyl linkages in both linear and branched *N*-acetyllactosaminoglycan, the enzyme from *B. fragilis* cannot hydrolyze the β-galactosyl linkage of the $\rightarrow$GlcNAcβ1$\rightarrow$6($\rightarrow$GlcNAcβ1$\rightarrow$3)Galβ1$\rightarrow$4GlcNAc group. Another endo-β-galactosidase, purified from the culture medium of *Clostridium perfringens*, releases Galα1$\rightarrow$3Gal from the Galα1$\rightarrow$3Galβ1$\rightarrow$4GlcNAc group located at the nonreducing termini of the sugar chains of glycoconjugates. The glycon specificity of the enzyme is very strict and blood group B determinant cannot be hydrolyzed.

Endosialidase is purified from a bacteriophage K1. It hydrolyzes both *N*-acetylneuraminic acid polymers and *N*-glycolylneuraminic acid polymers in which sialic acid residues are linked by an α2$\rightarrow$8 linkage. The enzyme cannot hydrolyze oligomers smaller than tetrasaccharide and *O*-acetylated *N*-glycolylneuraminic acid polymers.

With the specificities shown in Table 1, endoglycosidases were quite useful for the structural study of sugar chains. For example, endo H cleaves all high mannose–type sugar chains but not complex-type sugar chains, which will be described later. Accordingly, this enzyme is effective in discriminating between the two subgroups of *N*-linked sugar chains. Endo D is effective in discriminating between two isomeric sugar chains:

$$\begin{aligned} \mathrm{R} \rightarrow\ & \mathrm{GlcNAc}\beta1 \rightarrow 2\mathrm{Man}\alpha1 \\ & \rightarrow 6(\mathrm{Man}\alpha1 \rightarrow 3)\mathrm{Man}\beta1 \\ & \rightarrow 4\mathrm{GlcNAc}\beta1 \rightarrow 4\mathrm{GlcNAc} \end{aligned}$$

and

$$\begin{aligned} \mathrm{Man}\alpha1 \rightarrow\ & 6(\mathrm{R} \rightarrow \mathrm{GlcNAc}\beta1 \\ & \rightarrow 2\mathrm{Man}\alpha1 \rightarrow 3)\mathrm{Man}\beta1 \\ & \rightarrow 4\mathrm{GlcNAc}\beta1 \rightarrow 4\mathrm{GlcNAc} \end{aligned}$$

in which R represents sugars, because the former is cleaved by the enzyme but the latter is not.

Glycosphingolipids are the major glycolipids found in animal tissues. Since all glycosphingolipids contain just one sugar chain in one molecule, isolation of a single glycosphingolipid is enough for the structural study of that glycolipid's sugar chain. A glycosphingolipid with a single sugar chain is still a mixture of different molecules, however, as a result of the structural heterogeneity characterizing the ceramide portion of the molecule. To alleviate this complicated situation, glycoceramidases are used to release the sugar chains of glycosphingolipids intact as oligosaccharides. The oligosaccharides can then be labeled as described for the oligosaccharides released from glycoproteins and fractionated by using appropriate methods (see Sect. 2.2).

As described later, the sugar chains of proteoglycans are unique and are called *glycosaminoglycans*. Many glycosaminoglycan chains in proteoglycans are linked to the serine residues, constructing the Ser-Gly-X-Gly sequence of core proteins through the Galβ1$\rightarrow$3Galβ1$\rightarrow$4Xyl group located at their reducing termini. Accordingly, these sugar chains can be almost quantitatively released as polysaccharides by alkaline borohydride treatment as described for *O*-linked sugar chains of glycoproteins. Structures of the released polysaccharides are then analyzed by using appropriate endoglycosidases, which cleave particular glycosidic linkages in sugar chains. Among them, several eliminases listed in

Tab. 2 Bacterial eliminases.

Table 2 have been most effectively used to analyze the detailed structures of proteoglycans. As shown in Fig. 2, all these enzymes cleave the amino sugar–uronic acid linkages of glycosaminoglycan and produce various disaccharides, summarized in Table 3. The enzymes in Table 2 differ in substrate specificity. For example, chondroitinase ABC cleaves both the sulfated GalNAcβ1→3GlcA and the sulfated GalNAcβ1→3IdoA linkages, while chondroitinase AC cannot cleave the sulfated GalNAcβ1→3IdoA linkage. On the contrary, chondroitinase B cleaves only the sulfated GalNAcβ1→3IdoA linkage. Chondroitinase C cleaves the SO_4 →6GalNAc1→3GlcA linkage but not the SO_4 →4GalNAcβ1→3GlcA and SO_4 →6(SO_4 → 4)GalNAc β 1 → 3GlcA linkages. Since the disaccharides in Table 3 can be mutually separated by high-performance liquid chromatography (HPLC) and quantitatively analyzed by using approximately 0.5 nmol of sample, molecular constructions of chondroitin sulfates, hyaluronic acids, heparins, and heparan sulfates can be analyzed in detail, including their structural heterogeneities.

Recently, endo-β-xylosidase and endo-β-galactosidase, which cleave the sugar–polypeptide linkage region of proteoglycans, were isolated from the midgut gland of a mollusk, *Patinopecten*. Since the enzymes cleave all glycosaminoglycans containing the Galβ1→3Galβ1→4Xyl group at their reducing termini, and the released polysaccharides contain reducing termini that can be tagged by ^{3}H or fluorescent groups, they will become useful tools for the study of proteoglycans.

2.2 Fractionation of Oligosaccharides

Acidic oligosaccharides containing sialic acids, phosphate, or sulfate can be fractionated by either paper electrophoresis or ion-exchange column chromatography. Gel permeation chromatography

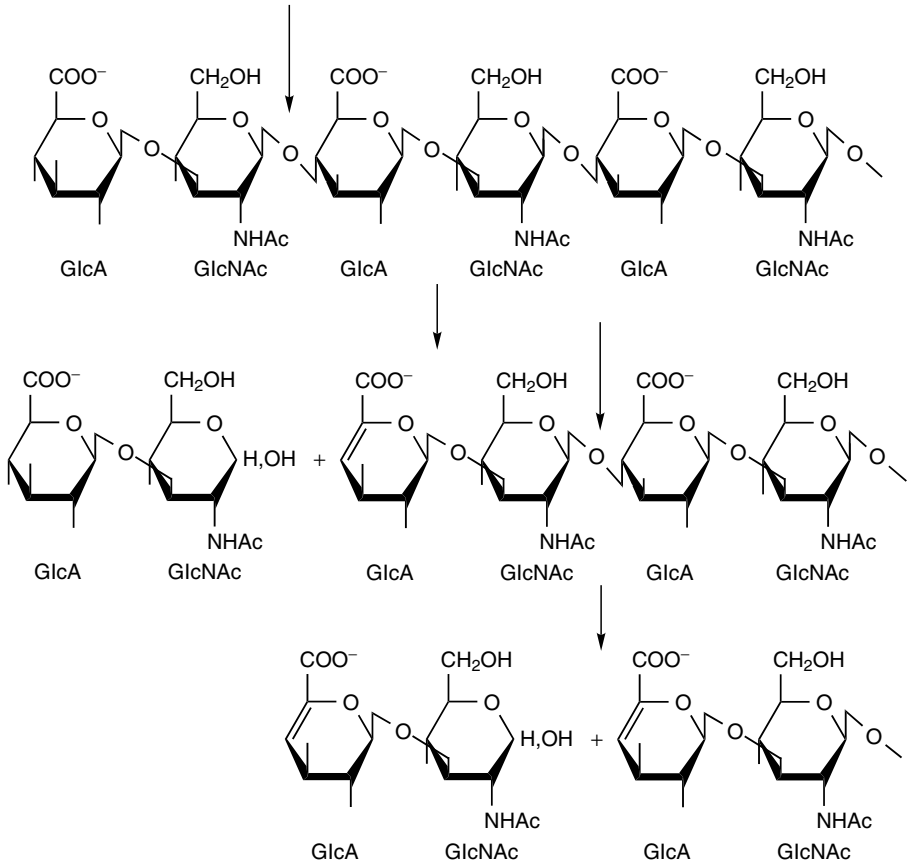

Fig. 2 Hydrolysis of hyaluronic acid by streptococcal hyaluronidase.

supplemented with ultrafine Bio-Gel P-4 and HPLC were also widely used. In addition, affinity chromatography with use of immobilized lectin columns offers a unique and effective method of fractionating oligosaccharides. Table 4 summarizes the binding specificities of immobilized lectin columns. Since the behavior of an oligosaccharide is mainly determined by the structural requirement of each immobilized lectin column and is not affected by additional sugar chain moieties, a mixture of many oligosaccharides can be separated into its components by means of an appropriately chosen series of lectin columns.

Two-dimensional mapping of known oligosaccharides, released from *N*-linked sugar chains by either glycopeptidase or hydrazinolysis, was reported. This method will be useful for obtaining an oligosaccharide pattern of *N*-linked sugar chains of a glycoprotein.

2.3 Structural Analysis of Oligosaccharides

The monosaccharide sequence of an oligosaccharide can be determined by sequential exoglycosidase digestion. Since an exoglycosidase releases a particular

monosaccharide from the nonreducing terminal of an oligosaccharide, the radioactivity or fluorescent groups incorporated at the reducing terminal of an oligosaccharide remains in the oligosaccharide portion until it has been completely digested to the tritium-labeled monosaccharide alcohol or fluorescent-labeled monosaccharide located at the reducing end. Because many exoglycosidases have narrow aglycon specificities, not only the sequence but also the linkage position of each monosaccharide can be determined by using such enzymes. For example, β-galactosidase purified from the culture medium of *Streptococcus pneumoniae* can cleave the Galβ1→4GlcNAc linkage but not the Galβ1→3GlcNAc and the Galβ1→6GlcNAc linkages. Therefore, the enzyme is an effective reagent for the determination of the Galβ1→4GlcNAc structure, which is widely distributed in many glycoconjugates. α-L-Fucosidase from *Bacillus fulminans* cleaves only the Fucα1-2*N*-acetyllactosamine group. In contrast, the enzyme from *Almond emulsin* cleaves Le^x and Le^a determinants, but cannot cleave other α-fucosyl linkages. The enzyme from the hepatopancreas of marine gastropods can cleave all α-fucosyl linkages. Accordingly, one can determine the position at which the α-fucosyl residue is linked by making proper use of these α-L-fucosidases.

Two α-mannosidases with different aglycon specificities were found in the mycellium of *Aspergillus saitoi*. α-Mannosidase I cleaves the Manα1→2Man linkage only. Accordingly, the enzyme is an effective reagent for identifying a series of high mannose–type sugar chains (see Sect. 3), which are all converted to Manα1→6(Manα1→3)Manα1→6(Manα1→3)Manβ1→4GlcNAcβ1→4GlcNAc by incubation with the enzyme. Another enzyme of *A. saitoi*, α-mannosidase II, is also useful because it releases one mannose residue from the R→Manα1→6(Manα1→3) Manβ1→ group but not from the Manα1→6(R→Manα1→3)Manβ1→ group. Therefore, the enzyme is an effective reagent when it is desired to assign

positions to the outer chains in a complex-type sugar chain (see Sect. 3).

In addition to the analytical techniques described so far, methylation analysis is essential for the complete structural determination of oligosaccharides. Smith degradation, which analyzes the periodate oxidation products of oligosaccharides, is also useful for the study of many oligosaccharides. Physical methods such

as nuclear magnetic resonance and fast atom bombardment mass spectrometry are also becoming useful techniques for the structural analysis of sugar chains.

3 Rules Detected in the Sugar Chain Structures of Glycoconjugates

Since the *N*-linked sugar chains found in glycoproteins usually contain more than 10 monosaccharides, the structural multiplicity represented is theoretically enormous. Indeed, it might be impossible to elucidate the biological information in sugar chains if we had to handle such a large number of isomers. Fortunately, studies of the sugar chain structures of various glycoproteins have revealed that a series of structural rules exists in them, and variable regions are limited to parts of their structures.

The *N*-linked sugar chains of glycoproteins contain as a common core the pentasaccharide Manα1→6(Manα1→3) Manβ1→4GlcNAcβ1→4GlcNAc, which we shall call the ''trimannosyl core''. On the basis of the structures and locations of the sugar residues added to the trimannosyl core, *N*-linked sugar chains are classified into three subgroups (Fig. 3). Complex-type sugar chains contain no mannose residues other than those in the trimannosyl core. Outer chains with an *N*-acetylglucosamine residue at their reducing termini are linked to the two α-mannosyl residues of the trimannosyl

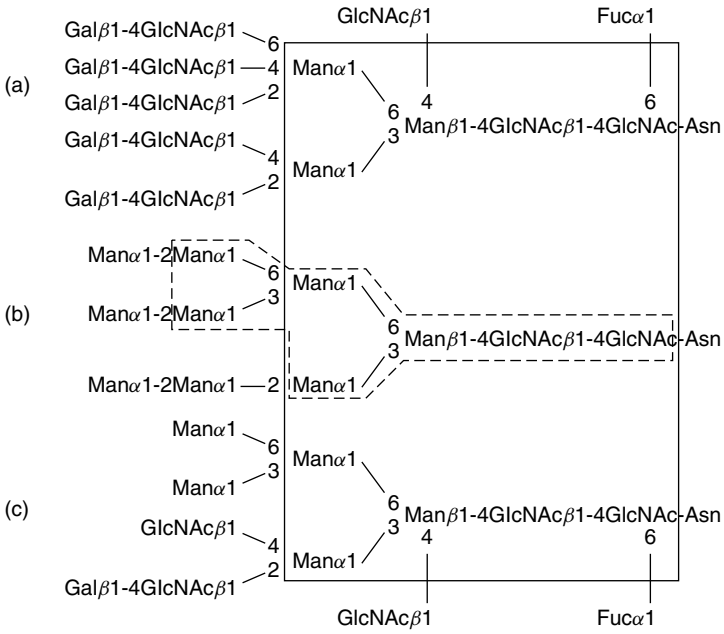

Fig. 3 Three subgroups of *N*-linked sugar chains: (a) complex-type; (b) high mannose–type; (c) hybrid-type. Within solid lines are the trimannosyl core structures common to all *N*-linked sugar chains. The structure enclosed by dashed lines is the common heptasaccharide core of high mannose–type sugar chains; for structures outside, variation in sugar chains is possible.

core. High mannose–type sugar chains contain only α-mannosyl residues in addition to the trimannosyl core. Manα1→6(Manα1→3)Manα1→6(Manα1→3)Manβ1→4GlcNAcβ1→4GlcNAc is commonly included in this type of sugar chain (enclosed by a dashed line in Fig. 3). Hybrid-type sugar chains were so named because they have the characteristic features of both complex- and high mannose–type sugar chains. One or two α-mannosyl residues are linked to the Manα1→6 arm of the trimannosyl core, as in the case of the high mannose–type, and the outer chains found in complex-type sugar chains are linked to the Manα1→3 arm of the core. Presence or absence of the α-fucosyl residue linked to the C-6 position of the proximal *N*-acetylglucosamine residue and the β-*N*-acetylglucosamine residue linked to the C-4 position of the β-mannosyl residue of the trimannosyl core (bisecting GlcNAc) contributes to the structural variation of complex-type and hybrid-type sugar chains.

Among the three subgroups of *N*-linked sugar chains, the largest structural variation resides in the complex-type sugar chains. This variation is formed by two structural factors. As shown in Fig. 4(a), mono-, bi-, tri-, tetra-, and pentaantennary sugar chains are formed by adding one to five *N*-acetylglucosamine residues to the trimannosyl core. Two isomeric triantennary sugar chains, containing either the GlcNAcβ1→4(GlcNAcβ1→2)Manα1→3 group or the GlcNAcβ1→6(GlcNAcβ1→2)Manα1→6 group, are found. These isomeric sugar chains are called 2,4-branched and 2,6-branched triantennary sugar chains respectively. On these *N*-acetylglucosamine residues, various outer chains are formed (Fig. 4b) by the concerted action of many glycosyltransferases and sulfotransferases. It is important to note that bisecting GlcNAc is never elongated by the action of glycosyltransferases. A combination of the antennary and the various outer chains will form a large number of different complex-type sugar chains. In most glycoproteins, the α-fucosyl residue linked at the C-6 position of the proximal *N*-acetylglucosamine residue of the trimannosyl core is not elongated by other sugars. However, it was found that the fucosyl residue of the hybrid-type sugar chain of octopus rhodopsin is substituted by a β-galactosyl residue at its C-4 position.

In contrast to *N*-linked sugar chains, *O*-linked sugar chains have fewer structural rules. At present, the latter chains are grouped into the six classes by their core structures, as shown in Fig. 5. *O*-Linked sugar chains with the cores 5 and 6 are found in a limited number of glycoproteins.

More than 200 glycosphingolipids, which are different in their sugar moieties, have been isolated from mammalian tissues. Most of these glycosphingolipids fall into five groups by virtue of their tetrasaccharide core structures (Fig. 6). In addition to these major groups, there are minor groups containing trisaccharides, disaccharides, and galactose as common cores. These glycosphingolipids are formed by a complicated biosynthetic network. Figure 7 summarizes the biosynthetic pathway of gangliosides, the generic name for glycosphingolipids containing a sialic acid residue. Although the structures of the gangliosides listed in Fig. 7 are well elucidated, the biosynthetic pathways leading to some of them have not been established.

Although proteoglycans should also be considered to be glycoproteins inasmuch as sugar chains are linked to protein cores, their sugar chains, called glycosaminoglycans, are much longer

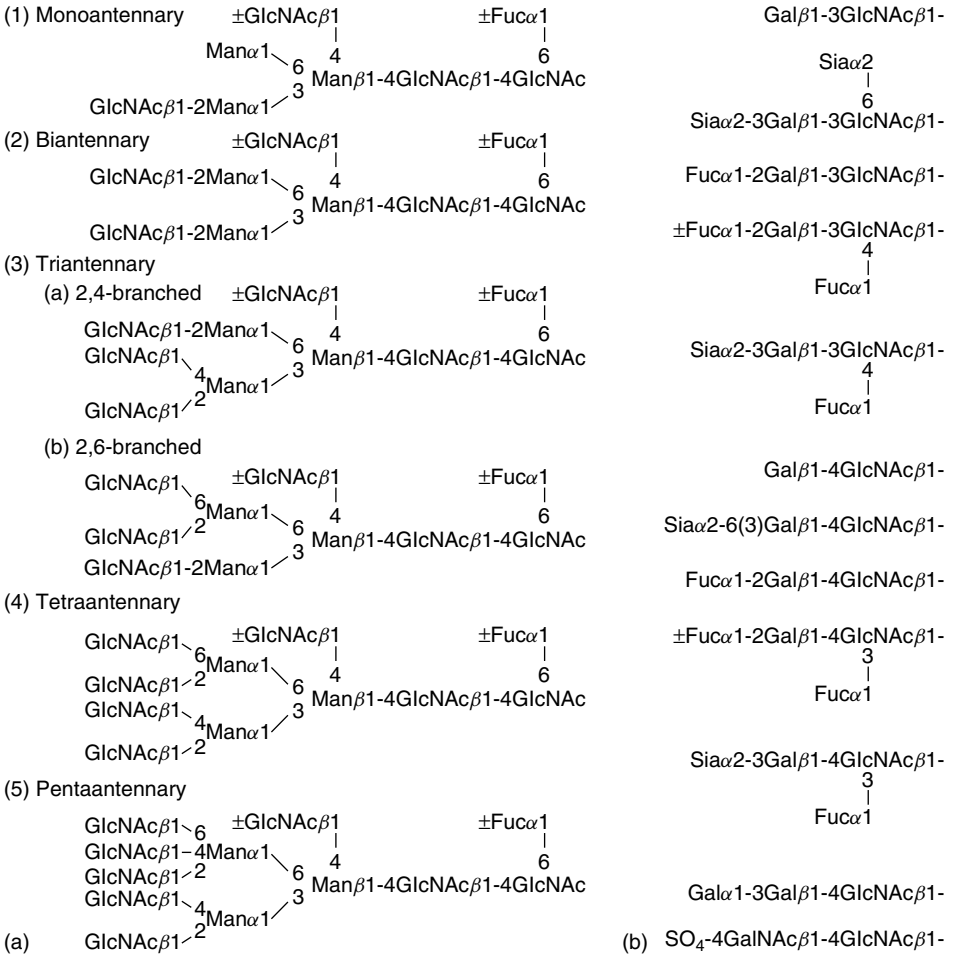

Fig. 4 Two major elements in the formation of the various structures of complex-type sugar chains: (a) branching of complex-type sugar chains and (b) various outer-chain structures found in complex-type sugar chains.

(100–200 monosaccharide residues) than regular *N*- and *O*-linked sugar chains and contain many anionic residues, such as uronic acid and sulfate. Furthermore, their structures are unique in that their basic construction is disaccharide repeats. On the basis of the disaccharide structures, glycosaminoglycans have long been classified into six groups: hyaluronic acids, chondroitin 4-sulfates, chondroitin 6-sulfates, dermatan sulfates, heparan sulfates, and keratan sulfates. However, detailed study of the structures of glycosaminoglycans has revealed that many microheterogeneities occur in the sugar chains, and it is rather hard to discriminate chondroitin 4-sulfates, chondroitin 6-sulfates, and dermatan sulfates because of the occurrence of their hybrid structures. Accordingly, glycosaminoglycans are currently classified into four groups as shown in Fig. 8.

4
Functional Roles of the Sugar Chains of Glycoconjugates

Accumulation of information about the structural characteristics of glycoconjugate sugar chains has enabled us to consider their functional roles in molecular terms. Glycoconjugates are distributed widely inside and outside the cells of multicellular organisms. Furthermore, the molecular construction of a single glycoconjugate group is quite variable. Figure 9 presents the molecular structures of three typical glycoproteins. Two different types of glycoproteins are found as extracellular components. Many serum glycoproteins have a limited number of sugar chains in one molecule (as in Fig. 9a). Many epithelial cells lining the alimentary tract and the respiratory tract secrete viscous glycoproteins called *mucins*. These glycoproteins work to protect the surface of mucous membrane from invasion of various pathogenic bacteria and viruses. As shown in Fig. 9(c), mucins have many short sugar chains, which are distributed all over the polypeptide moiety or are in clusters. Most of the cell-surface receptors are plasma membrane-integrated glycoproteins. They are anchored in the phospholipid bilayer by their hydrophobic amino acid cluster portion, and the sugar chains are linked to the polypeptide portion extended outside the cells (Fig. 9b). Although the functional roles of the sugar chains of glycoproteins are not simple because of their structural multiplicity, it is possible to classify them

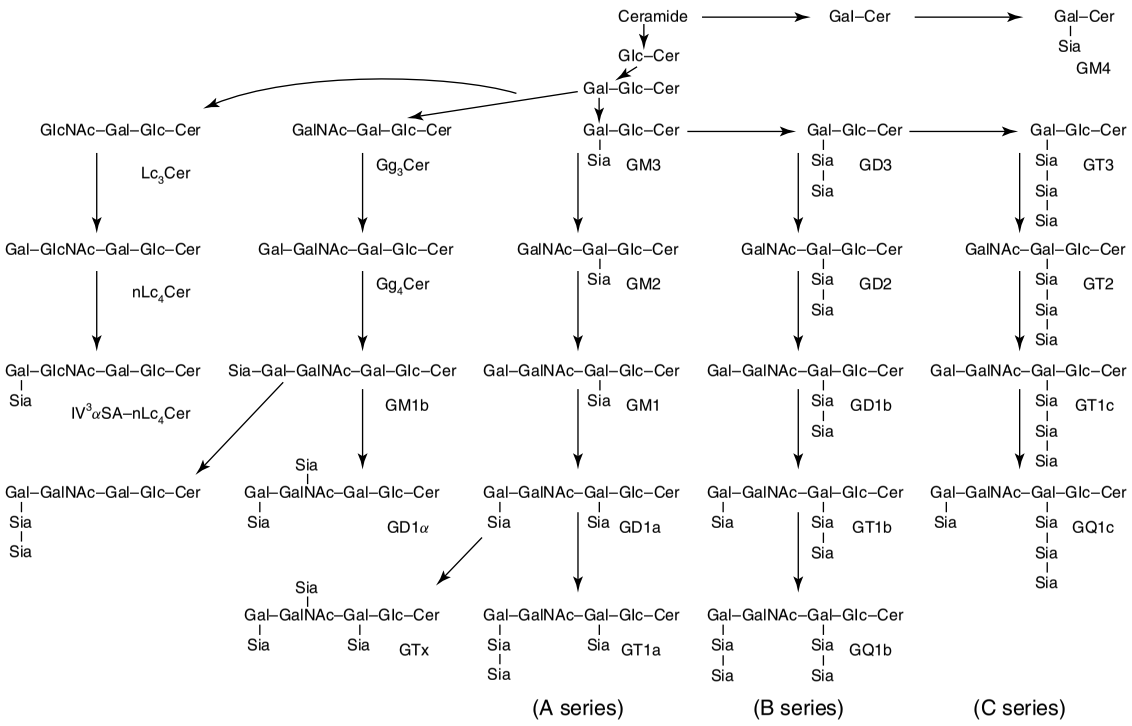

Fig. 7 Biosynthetic pathway of gangliosides.

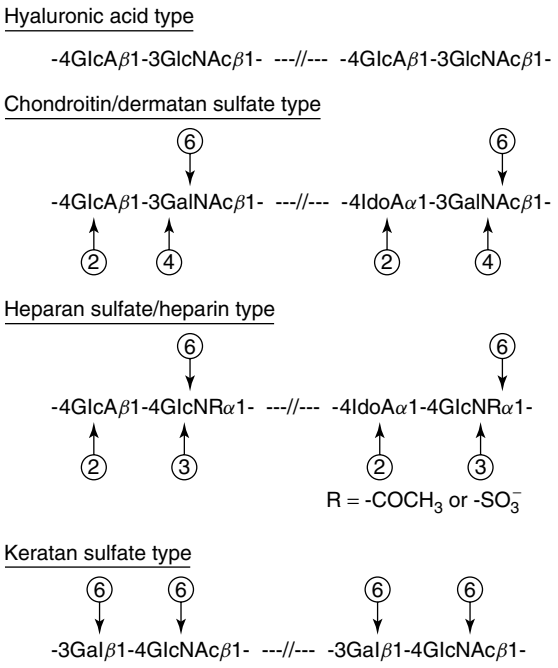

Fig. 8 Classification of glycosaminoglycans and their microheterogeneities. Except for hyaluronic acid, epimerization at the C-5 position of uronic acids and *N*- and *O*-sulfation (locations indicated by circled numbers) are the sources of microheterogeneities.

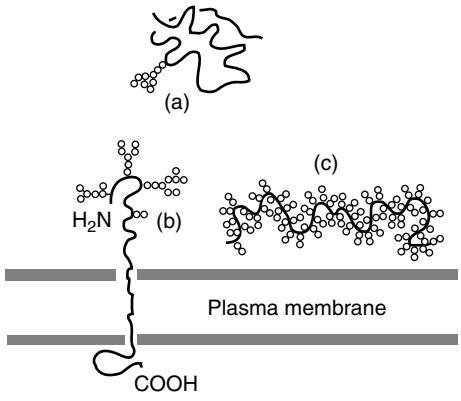

Fig. 9 Structural multiplicity of glycoproteins: (a) a serum glycoprotein, (b) a plasma membrane glycoprotein, and (c) a mucin. Open circles and black lines represent monosaccharides and polypeptide chains, respectively.

roughly into two groups: one that acts to confer physicochemical properties on proteins and another that acts as signals of various recognition phenomena.

Some of the representative functional roles of the sugar chains of glycoconjugates as recognition signals are introduced in the following parts of this section.

4.1 Glycoprotein Hormones

Four glycohormones have been known to occur in a variety of mammals. Three of them are produced in the same organ: lutropin and follitropin are produced by gonadotrophs, while thyrotropin is made

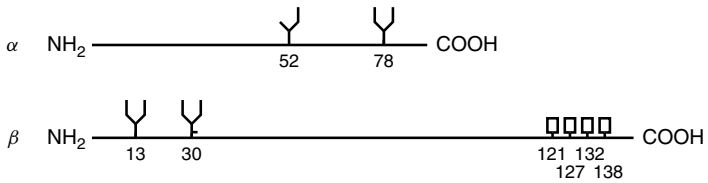

Fig. 10 Structure of hCG. Horizontal lines are polypeptide portions, trees are the *N*-linked oligosaccharides, and the boxes are the *O*-linked sugar chains.

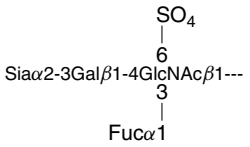
by thyrotrophs in the anterior pituitary. Chorionic gonadotropin (Fig. 10), however, is produced by placental trophoblasts. All these hormones are composed of two noncovalently linked subunits of different sizes, designated α and β. Since the α-subunits of all four glycohormones have an identical amino acid sequence within an animal species, the specificity of each hormone to bind to its target cells had been considered to reside in its β-subunit. However, elucidation of the structures of *N*-linked sugar chains of the four glycohormones revealed that the α-subunits of these hormones are not in fact the same.

Furthermore, deglycosylated human chorionic gonadotropins (hCGs), obtained by enzymatic digestion or chemical means, were found to express no hormonal activity even though they bind to the target cells more strongly than their natural counterparts. Therefore, the *N*-linked sugar chains of glycohormones might play crucial roles in the biological functions of these substances. Actually, comparative study of the biological activities of hCGs, in which only one of the *N*-glycosylation sites was eliminated by recombinant DNA technology, revealed that *N*-glycosylation at the Asn52 of the α-subunit is essential for the expression of hormonal activity, while removal of the *N*-linked sugar chains at either Asn13 or Asn30 of the β-subunit or Asn78 of the α-subunit had no effect. Another important evidence shown by this line of study is that removal of Asn78 glycosylation of the α-subunit markedly reduced its assembly with the β-subunit. Glycosylation of the two *N*-glycosylation sites of the β-subunit is not essential for its assembly with the α-subunit, but elimination of Asn30 glycosylation inhibits the secretion of uncombined β-subunit. These results indicated that the *N*-linked sugar chains of hCG are important for constructing the correct conformation of each subunit. That the presence of at least one *N*-acetylglucosamine residue at each of the four *N*-glycosylation sites of hCG is enough to keep the correct folding of the two subunits was shown two decades ago by investigating the effects of digestion with exo- and endoglycosidases on the folding and assembly of the two subunits.

4.2 Immunological Systems

It is known from recent studies in immunology that both cellular and humoral immunological systems are controlled by a complicated network connecting the interactions of immunocompetent cells. In response to soluble immunological and inflammatory factors, leukocytes adhere to each other and to cells of other types (e.g. platelets, vascular endothelial cells, etc.). These interactions are characteristic in that they quickly form a strong and temporary contact between cells within a relatively short period compared to

Fig. 11 Structure of the ligand of L-selectin.



the permanent cell adhesion observed in tissue-forming cells. Therefore, such interaction should be mediated by the special adhesive molecules that appear on the surface of activated cells.

Selectins were found by the studies to elucidate the mechanism that facilitates the recirculation of lymphoid cells from the intravascular compartment to lymph nodes. L-selectin, which is expressed on the surface of leucocytes, is considered to play an essential role in the homing of peripheral lymphocytes. The structure of its ligand was recently elucidated as sialyl-6-sulfo-Le^x (Fig. 11). P-selectin, which is expressed on the surfaces of activated platelets, megakaryocytes, and vascular endothelial cells, plays an important role in the early phases of leukocyte recruitment and adherence of activated platelets to neutrophils, monocytes, natural killer cells, and some subsets of T-lymphocytes. The ligands of P-selectin are rather complicated. They recognize both tyrosine sulfate residues of the polypeptide moiety and the sialyl Le^x residues of the sugar chains of the target cell-surface glycoproteins. A membrane-integrated glycoprotein that mediates the binding of monocytes and neutrophils was found on the surface of vascular endothelial cells. This glycoprotein called E-selectin is not constitutively expressed on the endothelial cells but is rapidly induced on the cells activated by the action of cytokines. Accordingly, the glycoprotein plays an important role in accumulating monocytes and neutrophils at the site of inflammation in an animal body. Adhesion of cells to E-selectin correlated with the presence on the cell surface of the Neu5Acα2→3Galβ1→3 or 4(Fucα1→4 or 3)GlcNAcβ1→ group.

Many intercellular mediators of glycoprotein nature were found to play roles in controlling the T-cells and a B-cell network. That the sugar chains work as ligands of these mediators and start their signal transductions was found. It was reported that a recombinant human interleukin-1β recognizes glycans of glycosylphosphatidylinositol anchor. That interleukin 2 recognizes high mannose–type sugar chains was also reported.

Immunoglobulin G (IgG) plays a major role in humoral immunity. It is unique among serum glycoproteins in that it contains sugar chains of extremely high microheterogeneity produced by the presence or absence of the two galactoses, the bisecting GlcNAc and the fucose residue underlined in the biantennary sugar chain in Fig. 12. In spite of this complex nature,

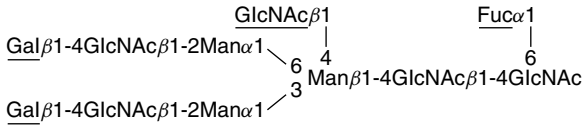


Fig. 12 The largest desialylated *N*-linked sugar chain of human IgG. Variation occurs in the presence or absence of the underlined sugar residues.

oligosaccharides of IgG samples purified from healthy human sera gave almost identical molar ratios. An interesting finding is that the IgG samples purified from sera of patients with rheumatoid arthritis are prominently lacking in galactose residues. This galactose deletion phenomenon in rheumatoid arthritis patients is limited to the sugar chains of IgG among serum glycoproteins and is induced by lower affinity of the β-galactosyltransferase in B-cells to UDP-galactose. The degalactosylated human IgG sample, obtained by *Streptococcus* 6646K β-galactosidase digestion, binds less effectively to the subcomponent C1q of the first component of the human complement and the Fc receptor. No decrease in binding to protein A was observed in the degalactosylated IgG. These results indicated that the function of IgG molecules can be modified by different degrees of maturation of their sugar moieties.

The data so far introduced indicated that glycobiology is indispensable for the future development of immunology.

4.3 Fertilization

Fertilization of mammals starts when a capacitized sperm meets a matured egg within an oviduct. Mammalian eggs are covered with a layer called *zona pellucida* (ZP), which is synthesized and secreted from the oocytes in developing follicles. It has been proposed that the ZP plays important roles in fertilization, including facilitation of species-specific recognition by sperm, prevention of polyspermy, and protection of fertilized eggs until the blastocyst stage.

In mice, the ZP is reported to be composed of three glycoproteins: ZP1, ZP2, and ZP3. It was reported that *O*-linked sugar chains, containing α-galactosyl residues at their nonreducing termini, of ZP3 work as sperm receptors. It was also reported that the β-galactosyltransferase on the sperm plasma membrane mediates sperm–egg binding by interacting with the sugar chains of ZP glycoproteins. The rationale of the latter hypothesis is partly proven by the finding in porcine ZP of the *N*-linked and *O*-linked sugar chains enriched in nonreducing terminal *N*-acetylglucosamine residues, which will interact with β-galactosyltransferase.

Occurrence of *N*-linked sugar chains with *N*-acetylglucosamines at their nonreducing termini was also found to occur in mouse testis. Targeted disruption of *Man2a2*, a gene encoding α-mannosidase IIx that is responsible for the processing of hybrid-type sugar chains to the Manα1→6(GlcNAcβ1→2Manα1→3)Manβ1→4GlcNAcβ1→4GlcNAc group: the core portion of complex-type sugar chains, resulted in male infertility. The infertility is induced because spermatogenic cells fail to adhere to Sertoli cells and are prematurely released from the testis to the epididymis. By investigating the structures of glycopeptides that inhibited germ cell/Sertoli cell adhesion, it was found that the nonasaccharide of spermatogenic cells shown in Fig. 13 is responsible for the attachment of the two cell lines. The receptor on Sertoli cells, which specifically binds to the nonasaccharide, remains to be investigated.

4.4 Recombinant Glycoproteins

As already described, many recombinant glycoproteins have been obtained by using various animal cell lines as hosts.

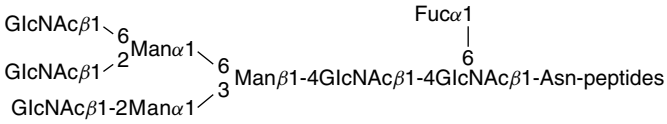

Fig. 13 Structure of the glycopeptide that inhibited adhesion of germ cells and Sertoli cells.

However, as evidenced through comparative study of the sugar chains of γ-glutamyltranspeptidases purified from the kidneys and livers of various mammals, both organ- and species-specific differences occur in the sugar chains of glycoproteins (Fig. 14). In addition, an altered glycosylation phenomenon is reflected in the sugar chains of recombinant glycoproteins because many of the cell lines used are somewhat malignant cells. Accordingly, the sugar chains of recombinant glycoproteins may display structural variations according to the type of cells used, even though the polypeptide structures are the same. Actually, comparative study of the *N*-linked sugar chains of natural human interferon-β1 (IFN-β1) and three recombinant IFN-β1s, produced by different cell lines transfected with the gene coding for human IFN-β1, revealed that their sugar patterns were different in spite of containing the same number of complex-type sugar chains. The differences occur both in the antennary structures and in the structures of outer-chain moieties. This phenomenon affords us a way to elucidate the function of the sugar chains by investigating the biological activities of several preparations of recombinant glycoproteins. Comparative study of the sugar patterns and the *in vivo* activities of several preparations of recombinant human erythropoietin revealed that the activity was proportional to the ratio of tetraantennary to biantennary oligosaccharides.

4.5 Unusual Sugar Chains

Sugar chains that link to the polypeptide moiety through Man-Ser and Thr linkages are found widely in yeast but are extremely rare in mammals. Investigation of the molecular mechanism of α-dystroglycan and laminin binding revealed that the sugar chains of α-dystroglycan shown in Fig. 15(a) are responsible for the binding. Therefore, finding of such unusual sugar chains as an important signal in the function of peripheral nerve dystroglycan may indicate that various unusual sugar chains occur as minor components in mammals and play important roles in particular tissues.

Notch signaling is an evolutionary conserved mechanism that is used by metazoans to control cell fates through local cell interactions. It is controlled by two ligand protein families called *Delta* and *Serrate/Jagged*. The binding affinities of Notch to the two ligands were further controlled by a protein called *Fringe*. It was found that Fringe is an *N*-acetylglucosaminyltransferase, which adds an *N*-acetylglucosamine residue to the α-fucosyl residues, linked to the serine residues of the epidermal growth factor (EGF) repeat of Notch. Addition of this *N*-acetylglucosamine residue will lead to further elongation of the sugar chains to the tetrasaccharide shown in Fig. 15(b). Fringe shows quite a high requirement of fucose residues and cannot add an

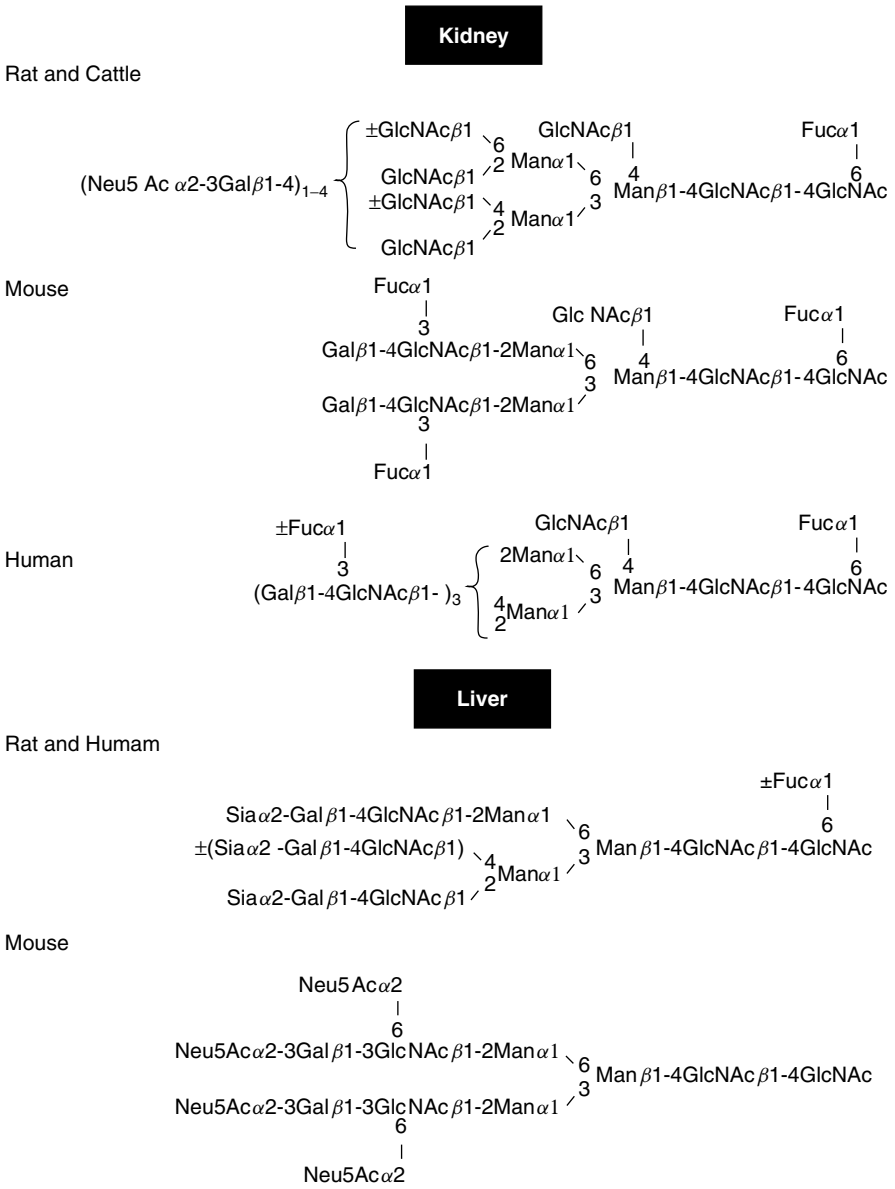

Fig. 14 Major sugar chain structures of γ-glutamyltranspeptidases purified from the kidneys and the livers of various mammalian species.

N-acetylglucosamine residue to any other sugar. It was recently found that the *N*-acetylglucosaminyltransferase, which adds the *N*-acetylglucosamine residue of the sugar chains of dystroglycan, acts only on the mannose residue linked to α-dysroglycan and cannot act on other α-mannosyl derivatives.

Neu5Acα2-3Galβ1-4GlcNAcβ1-2Manα1-Ser(or Thr)
(a)

Neu5Acα2-3Galβ1-4GlcNAcβ1-3Fucα1-Ser
(b)

Fig. 15 Structures of the sugar chains of (a) α-dystroglycan and (b) Notch.

These results indicated that the same trisaccharide residues are formed on different sugar chains by the action of various key isozymes and are used at different sites of differentiation of multicellular organisms. The trisaccharide residue is also distributed at the nonreducing termini of both *N*-linked and *O*-linked sugar chains. Therefore, structural elucidation of the receptors recognizing the trisaccharide residue is quite an interesting target for future study.

4.6
Blood Coagulation

Elucidation of the detailed structures of glycosaminoglycans is also opening a new age in proteoglycan study. Heparin was identified more than 70 years ago as an anti–blood coagulation material. A recent finding that a pentasaccharide structure in the heparin molecule, shown in Fig. 16, binds specifically to antithrombin led to the elucidation of the molecular mechanism of the anticoagulant activity of this glycosaminoglycan. With this finding as a turning point, many bioactive segments of glycosaminoglycans have been determined. Since blood clots are not formed on healthy blood vessel walls, some anticoagulation material may be included on the wall surfaces. On the basis of the observation that the introduction of heparinase solution into the bloodstream prominently decreases anticoagulation activity, occurrence of heparin-like sugar chains in the endoderm has been suspected. Actually, a heparan sulfate proteoglycan, which has a core protein different from that of heparin proteoglycan, is synthesized by the cultured endoderm obtained from bovine and rat artery. Another candidate anticoagulation factor is thrombomodulin found on the surface of endoderm. This protein binds to thrombin and suppresses its fibrin-clotting activity. A thrombomodulin–thrombin complex also enhances degradation of factors Va and VIIa by activating protein C. Accordingly, thrombomodulin protects the organism from thrombin overproduction. Upon chondroitinase ABC digestion, thrombomodulin was revealed to be a proteoglycan containing chondroitin sulfate. An interesting finding is that the activity of thrombin-dependent suppression of fibrin clotting is prominently decreased by

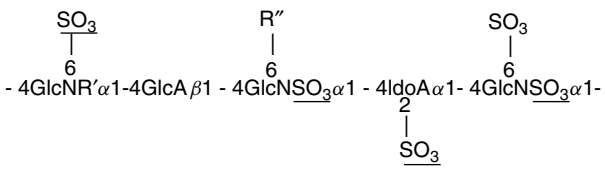

Fig. 16 Smallest unit of heparin necessary for binding to antithrombin III. R′ = either sulfate or acetyl residue. R″ = either hydrogen or sulfate residue. The four sulfate residues underlined in the figure are essential for the binding.

treating thrombomodulin with chondroitinase ABC, while thrombin-dependent protein C activation is not affected. This information will be effective in developing new oligosaccharide drugs in the near future.

4.7 Cartilage Formation

Cartilage is a tissue rich in extracellular matrix. Approximately 50% of the dry weight of cartilage is occupied by a proteoglycan called *aggrecan*. The structure of the core protein of aggrecan was elucidated by successful cloning of its cDNA. A lethal recessive mouse mutant, which is cartilage matrix–deficient (*cmd/cmd*), is an effective model that can be used in the investigation of the functional role of aggrecan. The skeleton of the embryo of this mutant is strikingly different from that of age-paired normal mouse embryo, and the limbs are drastically shortened and deformed. The mutant mouse was found to be genetically deficient in the biosynthesis of the core protein of aggrecan. When the mesenchymal cells obtained from normal mouse are cultured, they form nodules rich in extracellular matrix molecules. The cells within these nodules are round. Cultures of the mesenchymal cells of a *cmd* mouse also form nodules. However, these nodules are devoid of extracellular matrix, being simple clusters of cells of various types and sizes. When aggrecan is added to the culture medium, the cells from a *cmd* mouse form nodules similar to those observed in the normal cells' culture. Immunohistochemical observation of the apparently normalized nodules with use of antiaggrecan and anti-type II collagen antibodies revealed that these two molecules coexist in the extracellular matrix as in the case of nodules formed by normal cells. The level of fibronectin mRNA in the cultured *cmd* cells was four to eight times higher than that in the cultured normal cells, and abnormal accumulation of fibronectin was observed in the nodule. This abnormal formation of fibronectin in *cmd* cells was also suppressed to normal level by the addition of aggrecan. Treatment of aggrecan with chondroitinase ABC affected the observed activities. These data indicated that proteoglycan plays an essential role in the histogenesis of cartilage.

4.8 Sugar Chains of Glycolipids

It was found in 1971 that brain gangliosides bind cholera toxin and block its toxic effect on cells. Later, GM1 was found to be the major molecule participating in the expression of the inhibitory effect. Actually, GM1 in the plasma membrane of cells works as a receptor of cholera toxin, which will lead to penetration of the A-subunit of the toxin into the cells. The A-subunit then expresses the physiological effect of cholera toxin by triggering the activation of adenylate cyclase. In the decades that followed this discovery, several other bacterial toxins were reported to interact with particular gangliosides. However, the binding specificities of these toxins have not been well established, as in the case of cholera toxin.

Glycosphingolipids can be separated by thin-layer chromatography. Upon overlaying the plate with a homogeneous suspension of bacteria or viruses labeled with ^{125}I and washing the plate with buffer, one can use radioautography to detect glycosphingolipids that bind to the bacteria or viruses. This technique permitted the elucidation of the sugar chain structures required for binding to more than 12 bacteria and 14

viruses. Interestingly, some of the structures recognized by bacteria are located not in the nonreducing termini but within the sugar chains.

Functional aspects of the sugar chains of glycosphingolipids in mammalian cell differentiation have been mainly investigated on gangliosides. It was found that the ganglioside profile of HL-60 cells, a human promyelocytic leukemia cell line, changes differently according to the cells' differentiation to granulocytes and monocytes induced by dimethyl sulfoxide and a phorbol ester, respectively. Ganglioside GM3 increases remarkably by macrophage-like cell differentiation, while neolacto-series gangliosides increase by granulocytic differentiation. An important set of observations suggests that GM3 is a highly potent inducer, able to lead the monocytic differentiation of HL-60 cells, while neolacto-series ganglioside induces granulocytic differentiation of the cells.

5 Cloning of the Glycosyltransferases and Other Enzymes Related to the Formation of Sugar Chains of Glycoconjugates

Sugar chains of glycoconjugates represent the secondary gene products formed by the concerted action of glycosyltransferases. Regulation of the biosynthesis of sugar chains is under the control of the expression of various glycosyltransferases, their substrate specificities, and their location in specific tissue sites.

The importance of substrate specificities of glycosyltransferases was first evidenced by the study of an *N*-acetylgalactosaminyltransferase, which is responsible for the formation of blood group A determinant. This enzyme requires the presence of the Fucα1→2Gal group as its acceptor. Accordingly, A-enzyme cannot transfer an *N*-acetylgalactosamine residue to the Galβ1→3GlcNAc group (Type I chain) or the Galβ1→4GlcNAc group (Type II chain), which widely occurs in the sugar chains of glycoproteins and glycolipids. However, once a Fucα1→2 residue is added to the galactose moiety of these groups, they can be acceptors of the A-enzyme.

Le^b determinant in Fig. 17, however, cannot become an acceptor of the A-enzyme in spite of having the essential Fucα1→2Gal group. Therefore, the A·Le^b structure shown in Fig. 17 can only be made by the sequential action of H-, A-, and Le-enzymes.

In this biosynthetic scheme, A-enzyme and Le-enzyme compete for the same substrate sugar chain (H in Fig. 17). Accordingly, the oligosaccharide pattern that will be finally formed is controlled by the relative activities of the two enzymes expressed in a particular tissue.

Development of molecular biology opened the door of the gene-cloning age. Over 110 glycosyltransferases from various animal species were cloned by the year 2001. It had long been believed that each of the monosaccharide linkages including the anomeric structure in the sugar chains is formed by a particular enzyme. However, data obtained so far indicated that there are many cases in which a monosaccharide linkage is formed by multiple different glycosyltransferases. For example, at least six different α-fucosyltransferases were found to produce the Galβ1→4(Fucα1→3)GlcNAc group (Le^x determinant) from the Type II chain. This finding led to a conclusion that the Le^x determinants, which are known to widely

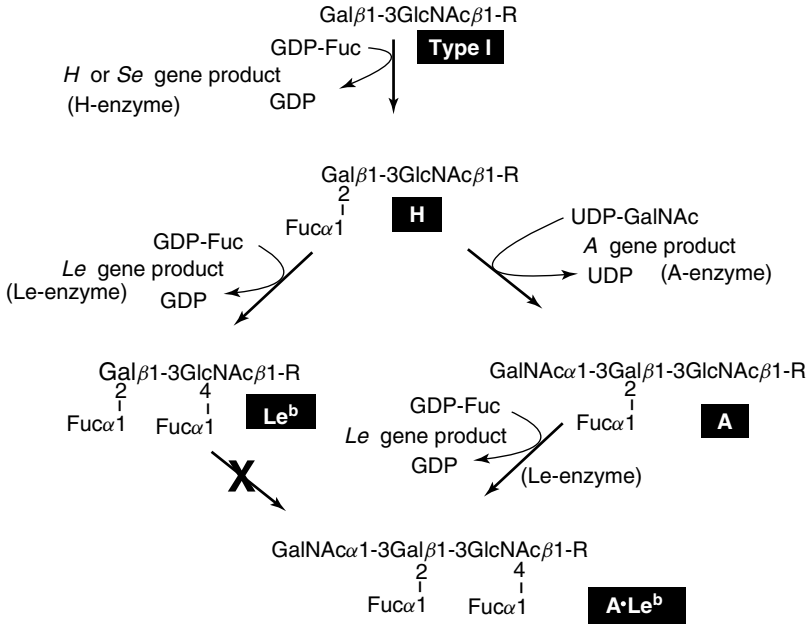

Fig. 17 Biosynthetic pathway of the A·Le^b blood group determinant.

occur in an animal body, are produced by different α-fucosyltransferases in different organs. A similar situation is found in the case of β-galactosyltransferases, which form the Galβ1→4GlcNAc group. At least seven different β-galactosyltransferases were found to catalyze the formation of the disaccharide group.

Another case of interest is found in the formation of *O*-linked sugar chains. As is evident from the structures of various *O*-linked sugar chains reported so far, formation of the GalNAcα1→Ser or Thr group in the polypeptide chains is the start to form various cores of *O*-linked sugar chains. At least nine distinct isoforms of the polypeptide α-*N*-acetylgalactosaminyltransferases (ppGalNAcTases-T1∼T9) were found to occur in mammals by the year 2001. Analysis of EST (expressed sequence tags) and genome databases suggested that additional forms of the enzyme remain to be characterized. By Northern blot analysis, it was confirmed that transcripts encoding ppGalNAcTase-T1 and -T2 are expressed in most rodents and in human tissues. ppGalNAcTase-T3 is found predominantly in human and murine testes, kidney, digestive, and reproductive tracts. The ppGalNAcTase-T4 transcript is highly expressed in rodent sublingual gland, stomach, and colon. ppGalNAcTase-T7 expression is similar to that of ppGalNAcTase-T4. ppGalNAcTase-T6 is highly expressed in human placenta and trachea. The ppGalNAcTase-T5 transcript is most abundant in murine sublingual gland and colon. The ppGalNAcTase-T9 transcript is found mainly in the murine sublingual gland, testes, and digestive and urogenital tracts. It was also found that the family of ppGalNAcTases is expressed in a unique spatial and temporal manner during murine development.

Only a subset of hydroxyamino acids are substituted with GalNAc in the mammalian glycoproteins. Thus, it was important to elucidate the enzymatic basis to determine which serines and threonines will become decorated with *O*-glycans. Studies of the kinetic properties of the expressed ppGalNAcTases from their cloned genes demonstrated that many of them have different substrate specificities toward polypeptide portions, which are partly overlapping. In addition, the expression patterns of various ppGalNAcTases in various tissues are different. Therefore, the initiation of mucin-type *O*-glycosylation appears to have a much more complex regulation than previously expected.

On the basis of the evidences so far described, organ-specific expression of a glycosyltransferase is now becoming an important target as a basis of the formation of the oligosaccharide pattern of a glycoprotein in the organ. In addition to this, elucidation of the mechanism of the different expression of one glycosyltransferase in different organs will be an important target, because of the presence of organ-specific glycosylation of a protein as evidenced by the study of γ-glutamyltranspeptidases (see Sect. 4.4 and Fig. 14).

A detailed study of the substrate specificities of glycosyltransferases including the structures of the polypeptide portions of the glycoprotein acceptors is also considered an important target in glycobiology, because there are many cases in which two glycoproteins produced by a single cell contain different sets of oligosaccharides. The phenomenon of site-directed glycosylation as evidenced in hCG may be explained by such studies.

Keywords

Glycoconjugate
Structure composed of at least one sugar residue linked to another compound such as protein or lipid.

Glycosidase
Any of the class of enzymes that hydrolyze glycosidic bonds.

Glycosyltransferase
Any of the class of enzymes that synthesize glycosidic bonds.

Glycosidic
Referring to the covalent attachment of, or to, sugar residues.

Glycan
Complex molecule composed in part of carbohydrate.

Oligosaccharide
Compound composed of several sugars residues linked together.

Lectin
Compound with affinity for binding sugar residues.

Interleukin
Term for a group of protein factors that affect primary cells and are derived from macrophages and T cells that have been stimulated by antigens or mitogens.

Cytokine
Substances that are produced by cells of the immune system and can affect the immune response.

Chemokine
Proinflammatory activation-inducible proteins that are mainly chemotactic for different cell types.

Proteosome
Multiprotein complex involved in the degradation of cellular proteins.

N-glycosidic
Referring to the linkage of sugars to nitrogen residues.

O-glycosidic
Referring to the linkage of sugars to hydroxyl residues.

Abbreviations

Dol, Dol-P, Dol-P-P:	dolichol, dolichol phosphate, dolichol pyrophosphate
Gal:	galactose
Glc:	glucose
GPI:	glycophosphatidylethanola
GalNAc:	N-acetylgalactosamine
GlcNAc:	N-acetylglucosamine
Man:	mannose
Fruc:	fructose
Fuc:	fucose
Sia, NeuAc, NANA:	sialic acid
GDP:	guanosine diphosphate
UDP:	uridine diphosphate
Asn:	asparagine

Modification of proteins through the addition of carbohydrates is one of the most significant alterations that occurs to these biological molecules and serves multiple purposes. Quite striking is the fact the protein glycosylation is controlled by factors that do not depend upon the information encoded in our genes. Sugar attachment is necessary in many proteins to ensure that they attain the proper folded state (i.e. structure) and thus, can carry out their intended functional roles. Equally important is the role glycosylation plays in the context of information. Cell surface glycoproteins are necessary for accurate and efficient cell–cell adhesion and cell–cell communication. The ability of certain families of proteins (lectins) to properly recognize the context of glycosylation on other structures (primarily proteins) is also critically important in cellular ''information exchange.'' In order to control the regulatory effects of glycosylation, the process can be in a constant state of flux, changing as cells differentiate. Probably, most telling is that many examples are known where disruptions in the pattern of glycosylation, as well as in the degradation of glycosylated proteins, lead to pathological conditions.

1 Introduction

The attachment of carbohydrate to proteins and lipids generates a class of molecules referred to as the glycoconjugates. Glycoconjugates are found on the cell surface, within the cytoplasm and nucleus, and circulate in the plasma. These molecules serve as important regulators of cell–cell communication, cell–cell adhesion and cell–cell recognition, modulation of immune responses, and regulation of many other biological processes such as coagulation. Attachment of sugar residues to proteins generates the specialized class of molecules called glycoproteins. Sugar attachment takes place both co- and post-translationally and is controlled by factors that do not depend upon the information encoded in our genes. At least 13 different carbohydrates have been identified attached to protein. These glycoprotein linkages include, N-glycosylation, O-glycosylation, glypiation (GPI bridge), C-mannosylation, and phosphoglycation. The most frequently occurring glycoprotein modifications are the N- and O-glycosylations that take place within the endoplasmic reticulum, Golgi, and cytosol.

The first description of carbohydrate linkage to protein was that of the N-glycosylation of the egg protein ovalbumin. Subsequently, numerous proteins have been shown to be modified by carbohydrate attachment and most of the commonly occurring monosaccharides have been found in these attachments. In fact, glycosylation of proteins as a functionally significant modification spans the spectrum of organisms from bacteria to plants to animals. The enzymes necessary for carrying out the attachment of sugars to proteins are collectively called glycosyltransferases and at least 16 of this class of enzymes have been identified. Enzymes are also necessary for the removal of sugars in the context of both carbohydrate remodeling and glycoprotein degradation. These latter enzymes are called glycosidases.

Membrane-associated carbohydrate is exclusively in the form of oligosaccharides covalently attached to proteins forming glycoproteins, and to a lesser extent, covalently attached to lipid forming the glycolipids. The predominant sugars found in glycoproteins are glucose (Glc), galactose (Gal), mannose (Man), fucose (Fuc), fructose (Fruc), *N*-acetylgalactosamine (GalNAc), *N*-acetylglucosamine (GlcNAc), xylose (Xyl), and *N*-acetylneuraminic acid (NANA or NeuAc); the latter being more commonly referred to as sialic acid (Sia). Figure 1 shows the symbols used to designate these sugars in the other figures. The distinction between proteoglycans and glycoproteins resides in the level and types of carbohydrate modification. The carbohydrate modifications found in glycoproteins are rarely complex: carbohydrates are linked to the protein component through either O-glycosidic or N-glycosidic bonds. The N-glycosidic linkage is through the amide group of asparagine. The O-glycosidic linkage is to the hydroxyl of serine (Ser), threonine (Thr), or hydroxylysine (Hyl) and in some cases, hydroxyproline (Hyp). The linkage of carbohydrate to hydroxylysine and hydroxyproline is generally found only in the collagens. The linkage of carbohydrate to 5-hydroxylysine is either the single sugar galactose or the disaccharide glucosylgalactose. In Ser- and Thr-type O-linked glycoproteins, the carbohydrate directly attached to the protein is most frequently *N*-acetylgalactosamine (GalNAc). The sugar directly attached to asparagines in N-glycosylations is most frequently *N*-acetylglucosamine (GlcNAc).

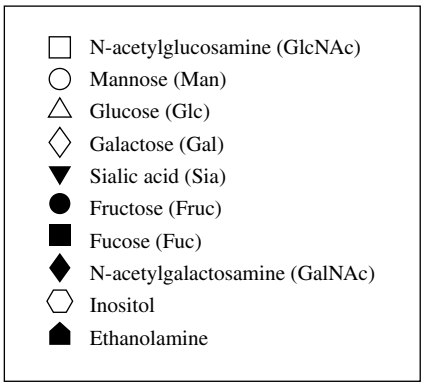

Fig. 1 Symbols used to depict the various carbohydrates, as well as other associated compounds, present in the structures described in Figs. 2 through 6.

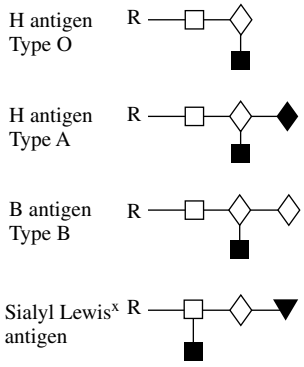

Fig. 2 Structures of the carbohydrates that constitute the ABO and sialyl Lewis^x antigens. ''R'' refers to either the protein or ceramide backbone of the ABO antigens. The ABO antigens are linked to proteins when they are secreted; they are linked to ceramides when present on plasma membranes. The ''R'' indicates the protein backbone where the carbohydrate antigen is directly added to asparagine residues in the typical GlcNAc-β-Asn linkage. When the ABO antigens are added to lipid, ''R'' represents the ceramide backbone of the membrane-associated glycosphingolipids.

That protein glycosylation is indeed an important component of cellular homeostasis is evidenced by the frequency of its occurrence, its requirement for protein structure and function, and the high degree of association between disease and abnormal glycoprotein synthesis and degradation. Further proof of the importance of protein glycosylation stems from an analysis of the degree of its occurrence. It has been estimated that when combining O-glycosylation and N-glycosylation of proteins, half of all proteins will eventually be identified as being carbohydrate modified.

In many cases, carbohydrates that are attached to proteins, and the structures they form when attached, are also found attached to lipids. A clinically and forensically relevant example of this overlap of modification between proteins and lipids is reflective of the ABO blood group antigens. The ABO blood group antigens are the carbohydrate moieties of glycolipids on the surface of cells as well as the carbohydrate portion of serum glycoproteins (Fig. 2). When present on the surface of cells, the ABO carbohydrates are linked to sphingolipid and are therefore of the glycosphingolipid class. When the ABO carbohydrates are associated with protein in the form of glycoproteins they are found in the serum and are referred to as the secreted forms of these antigens. Some individuals produce the glycoprotein forms

of the ABO antigens while others do not. This fact distinguishes the property of secretors from nonsecretors and this characteristic is the result of the action of the secretor (*Se*) locus.

The aim of this chapter is to review the types of protein glycosylation, the mechanisms of synthesis of the glycopeptide linkages, and the mechanisms involved in glycopeptide remodeling and degradation. In addition, the importance of carbohydrate recognition, through the actions of the animal lectins, will be discussed. An emphasis will be placed on the function of lectin activity in innate and acquired immunity reactions. In order to demonstrate the broad importance of protein glycosylation, numerous examples of the clinical relevance of carbohydrate synthesis and degradation will be presented. In addition, the therapeutic potential for inhibitors of glycosylation as well as the use of sugars themselves as treatment for certain conditions will be discussed. Recent advances in the field of glycobiology have demonstrated the relevance of the ''sugar code'' to medicine and indeed, this field is recognized as a major new discipline of medical significance.

2 Mammalian Glycopeptide Linkages

Most proteins that are secreted or bound to the plasma membrane are modified by carbohydrate attachment. The part that is modified, in plasma membrane–bound proteins, is the extracellular portion. Intracellular proteins are less frequently modified by carbohydrate attachment.

N-glycosidic bonds are the most widely found carbohydrate–protein linkages in animals. The β-glycosylamine linkage of *N*-acetylglucosamine (GlcNAc) to asparagine (Asn) in proteins represents the prominent form and is the site to which further attachment of a variety of complex and polymannose oligosaccharides occurs. The GlcNAc-β-Asn linkage is observed in a vast array of animal proteins including numerous hormones and plasma proteins, immunoglobulins, cell surface receptors, and the lectins. Although others sugars besides GlcNAc can be found attached to asparagine residues in prokaryotes, the only other non-GlcNAc N-glycosidic bond that has been found in mammalian proteins is the β-glucose linkage (Glc-β-Asn) observed in laminin.

O-glycosidic bonds represent the next most commonly occurring sugar-peptide bond found in animal proteins. The variety of proteins in which O-glycosylation is found is much greater than that for the N-glycosylated proteins. All hydroxylated amino acids (Ser, Thr, Hyl, and Hyp) can accept a sugar residue to become O-glycosylated. However, the most commonly occurring O-linkage is to serine and threonine. It should be noted as well that since hydroxyproline and hydroxylysine are prevalent in the collagens, these residues are frequently modified with sugar in the various functional collagen proteins. All vertebrate collagens contain galactose (Gal) attached to hydroxylysine in the Gal-β-Hyl linkage. The α-galactosamine linkage of *N*-acetylgalactosamine (GalNAc) to serine or threonine represents the predominant form of O-glycosylation in mammalian proteins. This linkage is considered the hallmark of the mucins that are glycoproteins and comprise the major portion of mucosal secretions.

The GlcNAc-β-Ser/Thr linkage is unique in that it is present in proteins found in the nucleus and cytoskeleton. Indeed, it

was the first sugar–protein linkage found to exist outside of the ER and Golgi synthesis and secretory machinery and this modification regulates protein function (see Sect. 3.2). Whereas, many other sugars can and are attached to the GalNAc-α-Ser/Thr structure, in the GalNAc-β-Ser/Thr setting, no other carbohydrates have been shown to be linked.

Several proteins of the coagulation cascade, as well as proteins that harbor a conserved domain first identified in epidermal growth factor (EGF), have been shown to be modified by either fucose (Fuc) or glucose (Glc) addition. Coagulation factors VII, IX, and XII each harbor the Fuc-α-Ser/Thr linkage. In these proteins, fucose is attached alone or serves as the branch for the attachment of a short oligosaccharide unit. The coagulation factors VII and IX also contain glucose attached in a β-linkage to serine. The Glc-β-Ser linkage is also found in another regulator of the coagulation cascade, thrombospondin.

Mannose (Man) is prevalently found linked to cell wall proteins in yeast and in bacteria. However, few examples of the Man-Ser/Thr linkage in mammalian proteins exist. The linkage of mannose has been shown in several proteoglycans and glycoproteins of neural origin. In addition, the α-dystroglycans of peripheral nerves have been shown to be O-mannosylated. These observations, limited though they may be, seem to suggest that O-mannosylation is a unique feature of glycopeptides of the nervous system. Mannose attachment through a carbon-carbon linkage to the C-2 of tryptophan (Trp) represents a novel glycopeptide linkage that has been observed in interleukin-12 and ribonuclease 2.

Many membrane-associated eukaryotic proteins are anchored in place by linkage to glycosylphosphatidylinositol (GPI). The components of the GPI linkage (Fig. 3) are quite variable and utilize both glycopeptide and glycophospholipid interactions to tether proteins to the cell surface. Although variable in structure, the GPI linkage does contain a core composed of phosphoethanolamine-6-Man-α1,2-Man-α1,6-Man-α1,4-GlcNAc-α1,6-*myo*-inositol-1-phospholipid implicating a conserved biosynthetic pathway in eukaryotes. The GPI linkage is most abundant in parasitic protozoa; however, several important mammalian proteins have been shown to be cell surface associated via the GPI linkage. These include lymphoid cell

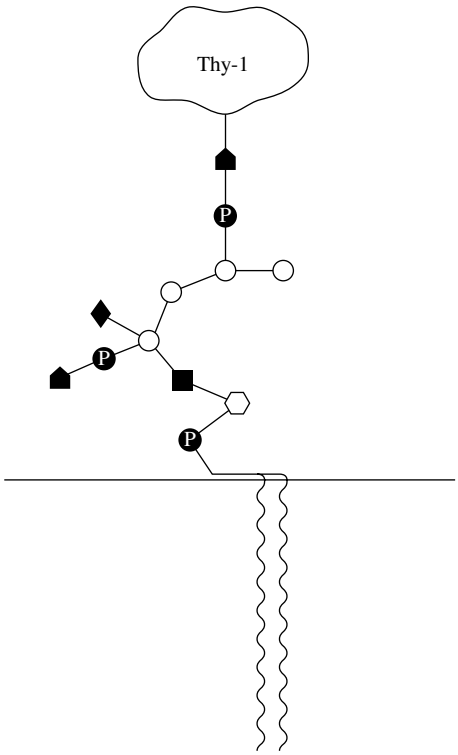

Fig. 3 Structure of the linkage of Thy-1 (CD90) to the GPI anchor. Definitions of symbols used are defined in Fig. 1.

antigens such as thymocyte antigen-1, Thy-1 (also identified as CD90), and lymphocyte function associated antigen-3, LFA-3; cell adhesion molecules such as neural cell adhesion molecule, *N*-CAM; and hydrolytic enzymes such as acetylcholinesterase and 5'-nucleotidase.

Of clinical significance is the erythrocyte GPI-anchored protein, CD55 (also termed *decay accelerating factor*, (DAF). The naming of proteins with the designation CD followed by a number originated from the use of antibodies to cell surface markers to phenotype or sort cells. These cell surface markers were termed *cluster of determination* (CD) *antigens*. Loss of CD55 leads to increased red cell lysis (hemolysis) with a concomitant increase in urinary excretion of hemoglobin. This disorder is termed *paroxysmal nocturnal hemoglobinuria* (PNH).

The most complex peptide-sugar linked molecules in the body are the proteoglycans. Proteoglycans are composed of a core protein (numerous types), a linker protein and glycosaminoglycans (GAGs). GAGs are long unbranched polysaccharides containing a repeating disaccharide unit. The disaccharide units contain either of two modified sugars, GalNAc or GlcNAc, and a uronic acid such as glucuronate or iduronate. The GAGs include hyaluronates, chondroitin sulfates, dermatan sulfates, keratin sulfates, heparin sulfates, and heparins. The core proteins of cartilage are known as aggrecans. Owing to the high negative charge of GAGs and their extended conformation, these molecules impart high viscosity to the environment in which they reside. Proteoglycans are located primarily on the surface of cells or in the extracellular matrix (ECM). The primary GAGs present in proteoglycans are hyaluronates, keratin sulfates and chondroitin sulfates. The GAGs themselves are attached to a carbohydrate linker that is O-glycosylated at serine or threonine residues. Some forms of the keratin sulfates are linked to the protein core through an *N*-asparaginyl bond. The protein cores of proteoglycans are rich in serine and threonine residues that allow for multiple GAG attachments.

There are numerous enzymes involved in the generation of peptide–glycosyl bonds as well as the additional carbohydrate–carbohydrate linkages that occur following formation of a glycopeptide linkage. These enzymes are collectively referred to as glycosyltransferases. At least 16 enzymes have been identified in various organisms that are responsible for the attachment of sugar to protein (8 mammalian enzymes are

Tab. 1 Mammalian glycosyltransferases involved in the synthesis of carbohydrate to protein linkages.

Enzyme	*Donor*	*Linkage*
Oligosaccharyl-transferase	$Glc_3Man_9GlcNAc_2$-PP-Dol	GlcNAc-β-Asn
GalNAc-transferase	UDP-GalNAc	GalNAc-α-Ser/Thr
GlcNAc-transferase	UDP-GlcNAc	GlcNAc-β-Ser/Thr
Fuc-transferase	GDP-fucose	Fuc-α-Ser/Thr
Xyl-transferase	UDP-xylose	Xyl-β-Ser
Gal-transferase	UDP-galactose	Gal-β-Hyl
Man-transferase	GDP-Man	Man-α-Trp
Glycogenin	UDP-glucose	Glc-α-Tyr

listed in Table 1). In almost all situations, the sugar–protein linkage is formed by the direct enzymatic transfer of an activated monosaccharide to a specific amino acid residue. Exceptions to this include the GPI linkage and formation of the GlcNAc-β-Asn linkage (see Sect. 3.2). Oligosaccharides are then generated through the sequential attachment of additional sugars via the activities of various glycosyltransferases.

3 Glycoprotein Synthesis

3.1 Synthesis of N-linked Glycopeptides

The predominant carbohydrate attachment in glycoproteins of mammalian cells is via addition of GlcNAc to asparagine residues forming the N-glycosidic linkage. The site of carbohydrate attachment in N-linked glycoproteins is found within a strict consensus sequence of amino acids, Asn-X-Ser/Thr, where X is any amino acid except proline. In addition, the presence of glutamic acid or tryptophan residues at the X position of the consensus reduces or eliminates glycosylation. When an analysis of proteins in the public databases is carried out, it can be shown that approximately 65% of all the proteins contain at least one occurrence of the Asn-X-Ser/Thr consensus. Of course, the presence of the consensus does not ensure that the native protein will indeed be glycosylated.

The formation of the GlcNAc-β-Asn linkage occurs in the ER through co-translational addition of a preassembled carbohydrate core structure that is delivered via a carbohydrate–dolichol lipid intermediate. The preassembled carbohydrate core structure comprises three terminal residues of glucose attached to a branched cluster of nine mannose residues that are in turn attached to two GlcNAc residues attached to the isoprenoid-like lipid, dolicholpyrophosphate. The structure is abbreviated $Glc_3Man_9GlcNAc_2$-P-P-dolichol. This structure is commonly referred to as the *lipid-linked oligosaccharide* (LLO), whereas the oligosaccharide structure itself ($Glc_3Man_9GlcNAc_2$) is termed the *en bloc* oligosaccharide. In mammalian cells, the importance of the terminal glucose residues is evident from the fact that transfer of $Man_9GlcNAc_2$-P-P-dolichol is some 25 times less efficient than the complete structure. In addition, structures that contain three terminal glucose residues, but not the complete $Man_9GlcNAc_2$ structure, are efficiently transferred to protein by oligosaccharyl-transferase.

Synthesis of the *en bloc* dolichol-P-P-oligosaccharide unit begins on the cytoplasmic face of the ER membrane and prior to transfer to the protein, the structure ''flips'' to the luminal side (Fig. 4). Sugars used for glycoprotein synthesis (both N-linked and O-linked) are activated by coupling to nucleotides. Glucose and GlcNAc are coupled to uridine diphosphate (UDP), and mannose is coupled to guanosine diphosphate (GDP). The first reaction in dolichol-P-P-oligosaccharide synthesis involves the formation of GlcNAc-P-P-dolichol with the release of uridine monophosphate (UMP) from the nucleotide-activated sugar, UDP-GlcNAc. The second GlcNAc and the Man-transferase reactions proceed via sugar transfer from the nucleotide-activated sugar directly to GlcNAc-P-P-dolichol. From this point, additional mannose residues are added to the $Man_1GlcNAc_2$-P-P-dolichol by transfer from Man-P-dolichol, which itself is formed from dolichol phosphate and GDP-Man.

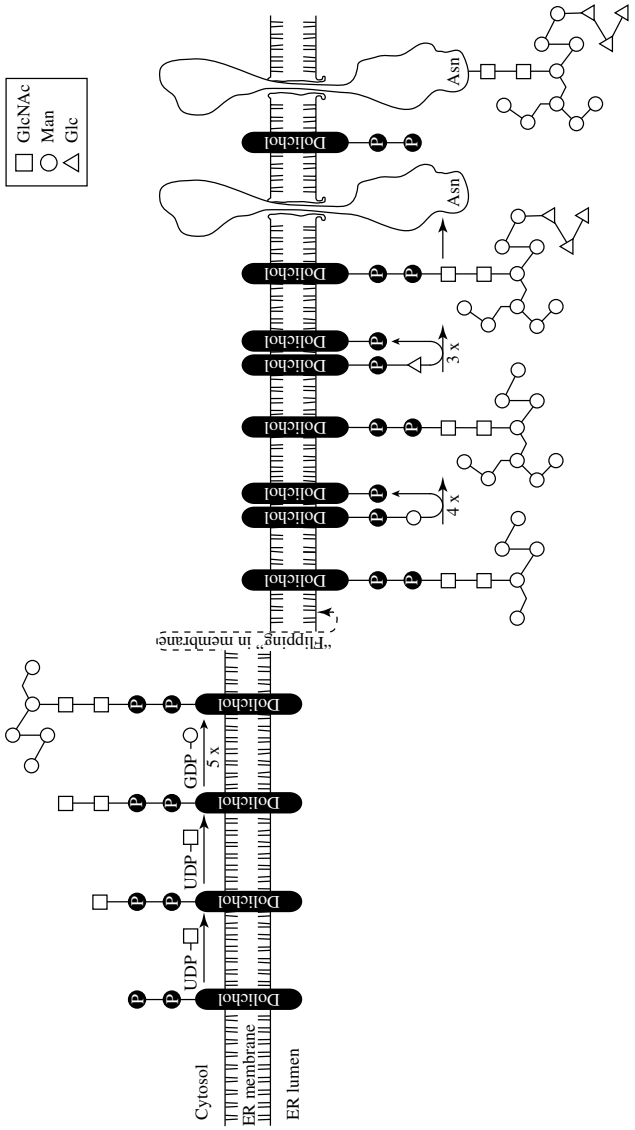

Fig. 4 Pathway for the synthesis and transfer of the *en bloc* oligosaccharide structure during N-glycosylation in the ER.

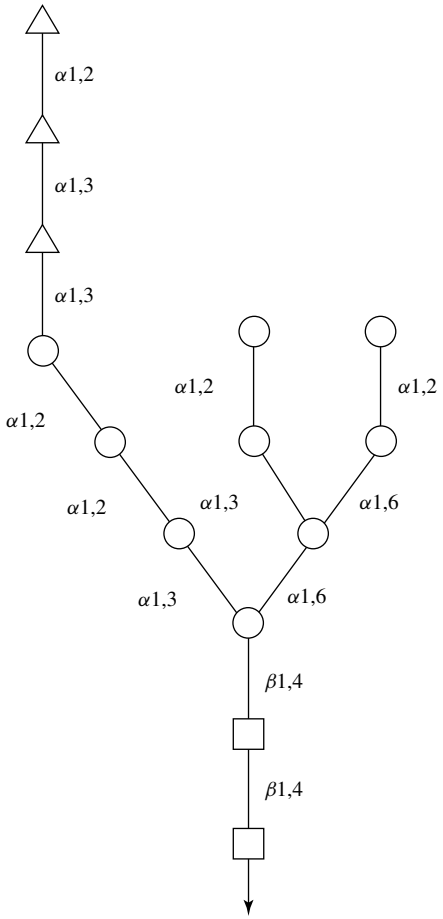

Fig. 5 Structure of the *en bloc* oligossacharide (also referred to as the *lipid-linked oligosaccharide, LLO*) attached in all N-linked glycosylation reactions. Refer to Fig. 1 for the identification of symbols used for sugar residues.

Immediately following transfer of the *en bloc* oligosaccharide (Fig. 5) unit to the protein, processing and alteration of the composition of the oligosaccharide ensues and continues as the protein passes through the ER then into and through the Golgi apparatus. Initially, the terminal glucose is removed through the action of glucosidase I (GI), a membrane-bound enzyme recognizing α1,2-linked glucose. The remaining two glucose residues are then removed by glucosidase II (GII), a soluble enzyme recognizing α1,3-inked glucose. After removal of the glucose residues, the action of α-mannosidases removes several mannose residues as the protein progresses to the Golgi.

The action of the various glucosidases and mannosidases leaves N-linked glycoproteins containing a common core of carbohydrate consisting of three mannose residues and two GlcNAc. Through the action of a wide range of glycosyltransferases and glycosidases, a variety of other sugars are attached to this core as the protein progresses through the Golgi. These latter reactions generate the three major families of N-linked glycoproteins: high-mannose type, complex type, and hybrid type (Fig. 6). High-mannose type contains varying amounts of mannose residues in addition to those contained in the core. Hybrid type contains various sugars and amino sugars. The complex type is similar to the hybrid type, but in addition, contains sialic acids in varying amounts.

3.2 Synthesis of O-linked Glycopeptides

The synthesis of O-linked glycoproteins occurs via the stepwise addition of nucleotide-activated sugars directly onto the polypeptide as opposed to the addition of *en bloc* synthesized oligosaccharide to asparagine residues in N-linked glycoproteins. The addition of sugar through linkage to serine or threonine residues occurs via the action of glycosyltransferases similar to those used in the synthesis of the N-linked glycoproteins. Attachment of sugars in O-linked glycoproteins

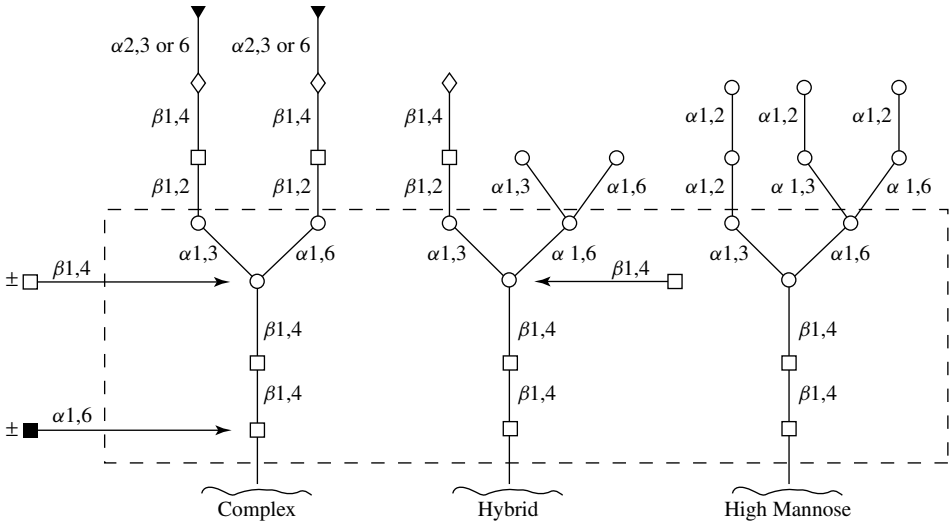

Fig. 6 Structures of the three main classes of N-glycans. Class is identified below each structure. Refer to Fig. 1 for identification of the symbols used for sugar residues. The core pentasaccharide structure common to all N-glycans is enclosed in the dashed rectangle.

occurs posttranslationally as the proteins pass through the Golgi. As for the sugars attached to N-glycans, O-linked sugars are nucleotide-activated prior to addition.

As discussed above, there are a wide variety of sugar linkages to amino acids harboring a hydroxyl moiety. However, the most commonly occurring linkage in mammalian O-glycans is GalNAc-α-Ser/Thr. There are at least nine GalNAc-transferases that have been identified and all are generally homologous to each other. Despite intensive investigation, no clear consensus sequence has been identified that directs the incorporation of GalNAc onto serine or threonine residues. A common theme does exist in that a preference for incorporation occurs near the amino terminus where there are clusters of serine/threonine residues within a β-turn and at a distance from charged amino acids. In addition, threonine residues appear to be the preferred substrates for GalNAc-transferases.

The formation of the GlcNAc-β-Ser/Thr linkage, catalyzed by *O*-GlcNAc transferase (OGT), is unique in several respects. First, this O-linkage is observed to occur in proteins that reside within the cytosol or the nucleus. Secondly, the enzyme glycosylates serine/threonine residues that are also sites for phosphorylation indicating that there may be some type of relationship or cyclical regulation between these two distinct types of protein modifications. Many transcription factors and RNA polymerase II are modified by *O*-GlcNAc linkage and when so modified the activity of these factors is repressed. More recently it was shown that OGT is recruited to transcriptional complexes by the transcriptional corepressor Sin3. The resultant *O*-GlcNAc modification of transcription factors in the complex leads to gene silencing.

4 Role of N-glycosylation in Protein Folding

Proteins that are destined to enter the secretory pathway of the cell must first attain a proper tertiary or quaternary structure. Failure to properly fold or to form the correct multi-subunit structure results in those peptides being retained in the ER and leads to their eventual degradation. As described above, following the addition of the *en bloc* synthesized oligosaccharide ($Glc_3Man_9GlcNAc_2$) to asparagine residues, the structure is the target for glucosidase (GI and GII) action. Removal of glucose from the *en bloc* oligosaccharide after it is attached to protein is a signal to the protein sorting apparatus that the protein is appropriately folded. In an apparent competition with the action of the glucosidases is the action of the glucosyltransferase, UDP-Glc:glycoprotein glucosyltransferase (GT). This enzyme adds glucose residues to the terminal mannose of $Man_{7-9}GlcNAc_2$ structures (i.e. the products of GI and GII activity as well as α-mannosidases). Quite strikingly, the activity of GT is higher toward misfolded glycoproteins than it is toward properly folded ones.

Many enzymes involved in protein folding, as well as several molecular chaperones, have been identified within the ER. Of particular import are the chaperones calnexin and calreticulin. Calnexin and calreticulin are homologous proteins with calnexin being membrane bound and calreticulin being soluble. Both of these chaperones recognize and bind to glycoproteins in the ER and are thus members of the larger class of proteins that recognize carbohydrate moieties termed *lectins*. Calnexin and calreticulin specifically bind to monoglucosylated oligosaccharides where the ideal substrate is $Glc_1Man_9GlcNAc_2$. After chaperone binding, the action of GII will lead to the liberation of calnexin and calreticulin. The oligosaccharide can then be reglucosylated by GT allowing the glycoprotein to once again be recognized by the lectin chaperones. This cyclic process of deglucosylation by GII followed by glucosylation by GT will continue until the protein achieves the proper folded conformation. Although important, it should be noted that the calnexin/calreticulin glycoprotein interaction system is not the only mechanism by which cells recognize and dispose of misfolded glycoproteins in the ER. The principal site for the degradation of misfolded soluble and membrane-associated glycoproteins is the proteasome.

5 Lysosomal Targeting by Specific Glycosylation

Enzymes that are destined for the lysosomes (lysosomal enzymes) are directed there by a specific carbohydrate modification. During transit through the Golgi apparatus a residue of GlcNAc-1-phosphate (GlcNAc-1-P) is added to the carbon-6 hydroxyl group of one or more specific mannose residues that have been added to these enzymes. The GlcNAc is activated by coupling to UDP and is transferred by UDP-GlcNAc:lysosomal enzyme GlcNAc-1-phosphotransferase (GlcNAc-phosphotransferase), yielding a phosphodiester intermediate: GlcNAc-1-P-6-Man-protein. A second reaction (catalyzed by GlcNAc 1-phosphodiester-*N*-acetylglucosaminidase) removes the GlcNAc leaving mannose residues phosphorylated in the 6 position: Man-6-P-protein. A specific Man-6-P receptor (MPR) is present in the membranes of the Golgi apparatus. Binding of

Man-6-P to this receptor targets proteins to the lysosomes.

Two distinct MPRs have been identified and both are members of the P-type lectin family. Both are type I integral membrane glycoproteins that contain an N-terminal extracellular domain, a single transmembrane domain, and a C-terminal cytoplasmic domain. One receptor is large with a molecular weight of approximately 300 kDa, the other receptor is smaller with a molecular weight of approximately 46 kDa. Structural similarities between these two receptors indicate that they are derived from a single ancestral gene with the larger receptor arising through multiple gene duplications. The extracellular portion of the larger receptor contains 15 repeating elements, each of which is highly similar to the extracellular domain of the smaller receptor. Both receptors exist as dimers embedded in the membrane.

The large receptor binds two moles of Man-6-P and the smaller binds 1 mol of Man-6-P per subunit, thus binding 4 and 2 mol of Man-6-P per dimer, respectively. The bovine and murine versions of the smaller receptors require divalent cations for ligand binding and thus the receptor has been termed the *cation-dependent Man-6-P receptor* (CD-MPR). However, the human counterpart may not require cations for its activity. The larger receptor does not require divalent cations for ligand binding and is therefore, commonly referred to as the *cation-independent Man-6-P receptor* (CI-MPR). However, the CI-MPR has been shown to bind the nonglycosylated polypeptide hormone, insulin-like growth factor II (IGF-II) and as such the larger MPR is more frequently identified as IGF-II/MPR. The IGF-II/MPR is available at the cell surface and its role in binding IGF-II is to target this hormone for degradation in the lysosomes. In addition to IGF-II, the IGF-II/MPR has been shown to bind a diverse array of Man-6-P-containing proteins as well as several nonglucosylated proteins. Although IGF-II/MPR and CD-MPR exhibit distinct activities, both receptors function to target newly synthesized lysosomal enzymes to the lysosomes.

The clinical significance of mannose phosphorylation for the proper targeting of enzymes to the lysosomes is evident from the identification of the molecular defect leading to the development of I-cell disease (mucolipidosis II, ML-II) and pseudo-Hurler polydystrophy (mucolipidosis III, ML-III). The characteristic physiological consequences of I-cell disease are severe psychomotor retardation and craniofacial abnormalities. The disease acquired its name due to the presence of large phase-dense inclusion bodies in the fibroblasts of afflicted individuals. Inheritance of defective GlcNAc-phosphotransferase, the first of the two enzymes required for Man-6-P synthesis, results in I-cell disease and ML-III.

6
Glycoproteins: Recognition and Homeostasis

6.1
Animal Lectins

The lectins are proteins that recognize and bind to specific types of carbohydrate structures displayed on other proteins and/or lipids. This class of protein does not, however, include the immunoglobulins, which are by themselves a specialized class of proteins that recognize carbohydrate. The basic definition of an animal lectin, therefore, describes nonimmunoglobulins that

are capable of differential agglutinization of erythrocytes. However, the lectins do not display enzymatic activity toward their respective substrates.

The contexts in which carbohydrate recognition occurs are quite diverse and as such, the lectins represent a broad group of proteins consisting of many unrelated families (Table 2). As the term lectin refers to proteins that can bind to carbohydrate, they all contain at least one primary carbohydrate recognition domain (CRD). Lectins often contain additional CRDs that allow for an increase in binding affinities of the primary CRD. In addition, several types of lectins attain carbohydrate-binding capabilities through oligomerization generating multivalent complexes.

Since carbohydrate recognition can be observed in a wide variety of biological contexts, the lectins constitute an extremely diverse group of proteins, many of which have no activity relationships other than the ability to bind carbohydrate. It is clear, therefore, that the biological activities associated with lectin binding are many (Table 3) and extremely important for numerous aspects of cellular homeostasis. Perhaps, the most important homeostatic function of the animal lectins is their role in the regulation of immune responses and autoimmunity. This latter fact will be the focus of the following review of several of the lectin families.

6.1.1 C-type Lectins

C-type lectins were initially defined as those proteins having a CRD of approximately 120 amino acids with a dependence on Ca^{2+} ions for binding activity. The dependence on Ca^{2+} for carbohydrate binding is demonstrated by the fact that

Tab. 2 Lectin families and their carbohydrate specificities.

Family	*Characteristics*	*Specificities*
C-type lectins (7 subfamilies)	Require Ca^{2+} for activity	Variable
Collectins (C-type subfamily III)	C-type CRD with collagen-like domains	Variable, mannose
Galectins (S-type lectins)	Sulfydryl-dependent or β-galactosidase binding	Strict for β-galactosides
Siglecs (I-type lectins)	Contain immunoglobulin-like domains	Sialic acid
Phosphomannosyl receptors (P-type lectins)	Recognize mannose-6-phosphate	Mannose-6-phosphate
Pentraxins	Quaternary structure composed of 5 identical polypeptides that form a ring with a central hole	Variable and can be noncarbohydrate
Calnexin and calreticulin	Recognition of properly folded glycoproteins in the ER	Glucose
Ficolins	Contain fibrinogen-like homology domain	Variable
Tachylectins	Distinct CRD but also contain fibrinogen-like domain	GlcNAc/GalNAc
ERGIC-53	Legume lectin-like fold	Mannose

Tab. 3 Functions associated with animal lectins discussed in the chapter.

Functions	*Lectin examples*
Cell–matrix interactions	Galectins
Cell–cell interactions	Selectins, galectins, I-type lectins
Cell migration, cell routing	Selectins, galectins, I-type lectins
Molecular chaperones in endoplasmic reticulum during glycoprotein synthesis	Calnexin, calreticulin
Recognition of foreign glycans, self/nonself recognition	Collectins, pentraxins
Intracellular trafficking of glycoprotein	P-type lectins
Regulation of cytokine release	Galectins, selectins
Anti-inflammatory actions	Galectins
Scavenging debris	Pentraxins

loss of the ion results in a conformational change in the CRD and subsequent loss of carbohydrate binding. The C-type lectin family can be further subdivided into at least seven subfamilies dependent upon the nature of other noncarbohydrate recognition domains as well as overall gene structure. C-type lectins recognize carbohydrate structures on many different forms of protein, including cell surface proteins and extracellular matrix (ECM) proteins and other ECM structures containing carbohydrate modifications such as proteoglycans, glycosaminoglycans, and glycolipids. C-type lectins also exhibit broad specificity in the types of ligands they bind including Fuc, Gal, Glc, GlcNAc, maltose, and Man and *N*-acetylmannosamine (ManNAc). One of the most important functions for carbohydrate recognition by C-type lectins is the role that function plays in pathogen recognition by the innate immune system.

The collectins are subtype III C-type lectins defined by having an additional collagen-like domain. The presence of the collagen-like domain allows the collectins to form a triple helical structure that creates a multivalent CRD, which lies at the carboxy-terminus of the protein. Mannan-binding lectin, MBL (also termed *mannose-binding protein*) is the best characterized human collectin. Although termed mannose-binding lectin, MBL actually exhibits higher affinity for GlcNAc than Man. Four additional collectins have been well characterized including lung surfactant proteins A (SP-A) and D (SP-D), collectin-43, and bovine conglutinin. The major function of the collectins is recognition of carbohydrate structures on microbial surfaces leading to activation of the complement cascade and phagocytosis.

The complement system is a host-defense mechanism that is engaged by both the innate and antibody-mediated (acquired) immune systems. Three pathways lead to complement activation; classic, alternative, and lectin. The classic pathway is activated by antibody–antigen complexes reflective of the function of complement in acquired immunity, whereas, the other two function in innate immunity. More than 30 plasma and membrane-bound proteins (identified by the letter C followed by a number) participate in the complement pathway. The classic pathway requires activation of C1q (a subcomponent of C1), whereas the lectin pathway involves activation of C2 and C4. MBL is synthesized by

the liver and secreted into the circulation. It is considered one of the acute-phase proteins synthesized by the liver. Expression levels of MBL rise in response to inflammatory signals. Upon binding to carbohydrate structures on microbial surfaces, MBL activates the complement system in a C4/C2-dependent manner, independent of C1q. The mechanism of MBL activation of complement requires the interaction of MBL with a family of serine proteases termed *mannose-binding lectin-associated serine proteases* (MASPs). The action of MBL-MASP in the lectin-activated complement cascade is similar to the C1q-antibody complex that activates the serine proteases C1r and C1s.

The selectins are subtype IV C-type lectins defined by the presence of the C-type lectin CRD, an epidermal growth factor–like domain and a variable number of complement regulatory protein-like repeat domains. The selectins are also members of the cell adhesion family of proteins. Each selectin is tethered to the plasma membrane via a single transmembrane domain. There are three characterized selectins that were originally identified as the adhesion molecules: endothelial–leukocyte adhesion molecule-1 (ELAM-1), murine lymph node homing receptor, and platelet granule membrane protein-140. These three proteins are now referred to as E-selectin, L-selectin, and P-selectin respectively.

A major function of the selectins is the recruitment of neutrophils to sites of inflammation. P-selectin is constitutively stored in secretory granules of platelets and endothelial cells. When stimulated by the appropriate response (e.g. IL-1 and TNF-α) these cells present P-selectin to the cell surface via fusion of the intracellular vesicles with the plasma membrane. Through this mechanism, P-selectin is involved in mediating very early responses of leukocytes to inflammatory signals. E-selectin is also synthesized by endothelial cells but is not constitutively present. Expression of E-selectin is regulated by cytokines such as IL-1 and TNF-α. L-selectin is expressed by most leukocytes and plays a role in the recruitment of these cell types into lymphatic tissue. Constitutively expressed L-selectin is rapidly released from the surface of activated leukocytes. Activation of L-selectin signaling, via ligand-induced cross-linking, results in potentiation of the responses of neutrophils to other stimuli. These effects are mediated by intracellular activation of both tyrosine and serine/threonine phosphorylations, the latter mediated through MAP kinases.

6.1.2 S-type Lectins: Galectins

The S-type lectins were originally so designated because the original family members exhibited a sulfhydryl-dependence on carbohydrate binding. The S-type lectins are now commonly referred to as the *galectins*. The galectins are all defined by a canonical CRD having an affinity for β-galactosides. To date, 14 galectins have been identified in mammals. The basic carbohydrate structures recognized by the galectins are an N-acetylated lactose (*N*-acetyllactosamine, LacNAc with the structure Galβ1,4GlcNAc). The galectins can be further divided into three subfamilies based upon their structures. The prototype subfamily (galectin-1, -2, -5, -7, -10, -11, -13, and -14) is comprised of a single CRD, the tandem-repeat type (galectin-4, -6, -8, -9, and -12) contains two homologous CRDs, and the chimeric type contains a single CRD combined with a unique amino or carboxy-terminus. The only mammalian chimeric type galectin thus far identified is galectin-3. The prototype galectins can

form noncovalent homodimers resulting in a functionally bivalent molecule, typified by mammalian galectin-1. Owing to their multivalent nature, galectins are capable of cross-linking glycoconjugates containing LacNAc structures. It is the effects of cross-linking that result in the initiation of biological responses to galectins. Galectin activities are observed both at the cell surface and intracellularly. All galectins are synthesized on soluble ribosomes and following synthesis, are targeted to specific locations including intracellular compartments and membranes or membrane-bound vesicles. The exact mechanisms by which galectins are secreted from cells remain unknown as none are synthesized with a canonical secretory signal sequence.

One of the most crucial functions of the galectins is in regulation of the inflammatory response. Galectin-1 is expressed by antigen-stimulated T cells, activated B cells, and by macrophages. The action of galectin-1 in these systems is to stimulate apoptosis resulting in cell death. Negative growth effects of galectin-1 are also seen in breast and prostate cancer cell lines. In addition to galectin-1, galectin-7, -8, -9, and -12 have been shown to exhibit proapoptotic activity. In contrast, galectin-3 exhibits antiapoptotic activities in similar types of cells. Whereas the proapoptotic effects of galectin-1 can be observed by adding the protein to activated T cells, the antiapoptotic effects of galectin-3 appears to be the result of intracellular activities associated with the protein. Interestingly, galectin-3 has some striking sequence similarities to the antiapoptotic Bcl-2 protein family.

Galectin-1 is a potent inhibitor of activated T-cell-mediated inflammatory responses. Using experimentally induced models of several autoimmune disorders (e.g. myasthenia gravis, multiple sclerosis, and rheumatoid arthritis) it has been shown that administration of recombinant galectin-1 can significantly ameliorate the resultant clinical symptoms. The potency of galectin-1 in these studies suggests that future advances will see clinical application of galectin-1 for the treatment of activated T-cell-mediated autoimmune diseases. Conversely, the presence of autoantibodies to galectin-1 has been identified in several neurodegenerative disorders. Likewise, the levels of autoantibodies to galectin-3 are inversely associated with severity of Crohn's disease (inflammatory bowel disease, IBD).

Expression of galectins and/or galectin-binding sites has also been correlated with various types of cancers as well as their severities. Elevated expression of galectin-1 has been shown to be correlated with the malignant potential of various cancers. Equally telling is the observation that survival potential from gliomas declines as the level of galectin-1 protein rises. Galectin-3 expression levels have also been shown to be elevated in gastric and liver cancers. In contrast, expression of galectin-8 declines during tumiorogenic progression.

It is clear from the data that the galectins exhibit activities ranging from cell adhesion, cell migration, proliferation, and differentiation, to roles in apoptosis and cancer. Emerging data indicates that galectins or galectin antagonists will find therapeutic use as anti-inflammatory mediators, immunosuppressants, or anti-cancer agents.

6.1.3 I-type Lectins: Siglecs

I-type lectin is the term collectively given to the family of carbohydrate-binding proteins that belong to the immunoglobulin (Ig) superfamily of proteins. The Ig superfamily of proteins all have at least

one domain composed of two β-sheets that are disulfide bonded and stacked together. There are at least three subtypes of Ig domain (V-set, C1-set, and C2-set) that are defined by the number and arrangement of the β-strands in the domain.

All of the I-type lectins are membrane anchored with their CRDs on the outside of the cell. The I-type lectins are divided into two main subfamilies. One subfamily includes the cell adhesion molecules, L1, *N*-CAM, and intercellular adhesion molecule-1 (ICAM-1) as well as the cell surface glycoproteins CD83 and CD2. The other subfamily is composed of the siglecs, which are so named because of their binding specificity for sialic acid residues. Siglecs are also characterized by the presence of a characteristic V-set Ig domain at their amino termini followed by varying numbers of C2-set domains.

The siglecs are primarily expressed on cells of the hematopoietic system. A macrophage lectin-like adhesion molecule termed *sialoadhesin* and CD22, and another member of the Ig superfamily that shows restricted B-cell expression were the first two members of the siglec group to be characterized. Both sialoadhesin and CD22 were shown to mediate cell–cell interactions through their abilities to recognize sialylated glycoconjugates. Sialoadhesin is now referred to as siglec-1 and CD22 as siglec-2 in reference to their being the first and second member characterized respectively. Although structurally different from the siglecs, the I-type lectins CD83 and cell adhesion molecule L1 also have been shown to bind to sialic acid residues. To date, at least 11 siglecs have been characterized. Siglec-3 was originally defined as CD33, a marker for cells of the myelomonocytic lineage. Several siglecs have been identified that are structurally very similar to siglec-3 and as such, they have all been classified as members of the CD33/siglec-3 subfamily of siglecs. This subfamily includes siglec-3, -5, -6, -7, -8, -9, -10 and -11.

Like the pentraxins (see Sect. 6.1.4) the siglecs, principally the siglec-3 family, are involved in regulatory aspects of innate immunity reactions. All of the siglec-3 family members contain a motif in their intracellular tails termed an *immunoreceptor tyrosine-based inhibitory motif* (ITIM) indicating that these proteins act as inhibitory receptors on hematopoietic cells. Associated with the ITIM is a tyrosine residue that becomes phosphorylated in response to activation of activating receptors. The function of the ITIM is to recruit phosphatases to activated receptor complexes, thereby deactivating the activating receptors by phosphate removal. Siglec-3 has been shown to interact with two inhibitory tyrosine phosphatases, SHP-1 and SHP-2, and this interaction requires the presence of phosphotyrosine and the ITIM. The presence of phosphotyrosine in the cytoplasmic tail of siglec-3 also enhances the subsequent interaction with sialylated ligands suggesting that tyrosine phosphorylation plays a regulatory role in ligand binding to siglec-3.

6.1.4 **Pentraxins**

The pentraxin family of lectins is defined by having primary sequence similarities to major acute-phase reactants, C-reactive protein (CRP) and serum amyloid P component (SAP). The pentraxins assume a characteristic multi-subunit complex consisting of 5 to 10 identical subunits that form a pentameric ring structure with a central open core, hence the term pentraxin. The original identity applied to CRP stems from the observation that it was an antibody-like molecule associated with the C polysaccharide component

of the *pneumococcal* bacterium. CRP was originally shown to be a complement-activating precipitin with a high affinity for phosphocholine. Although originally not identified as a carbohydrate-binding protein, CRP was found to exhibit affinity for galactans (galactose-containing oligosaccharides) and phosphogalactose using a binding site distinct from that involved in its precipitin activity. Similarly, SAP not only has carbohydrate-binding specificity it also has an affinity for phosphoethanolamine. In general, the pentraxins represent a class of molecules that exhibit calcium-dependent binding to a number of substances bearing phosphate esters and carbohydrates. Classes of pentraxins have been divided into those with binding similarities to CRP (i.e. preference for phosphocholines) or SAP (i.e. preference for phosphoethanolamines).

Another defining feature associated with pentraxins is the observation that their expression is markedly increased as a consequence of the activities of immunomodulatory molecules such as IL-1 and TNF-α as well as in response to tissue injury and necrosis. Both IL-1 and IL-6 can dramatically induce the acute-phase response of the liver leading to increased CRP synthesis and secretion. That these factors are important in the induction of CRP synthesis is demonstrated by the fact that IL-1 receptor antagonists or anti-IL-6 antibodies can both block CRP synthesis in cultured hepatic cells. Reciprocally, addition of CRP to human alveolar macrophages in culture induces the synthesis of IL-1 and TNF-α suggesting a feedback amplification of the response to proinflammatory cytokines.

A role for the pentraxins in innate immunity functions is suggested by their reactivities with the complement system as well as with phagocytic leukocytes. CRP is consistently shown to activate the classic complement pathway and binds to the site of complement-induced cell injury. In this system, it has been shown that CRP interacts with complement protein C1q and SAP with C4-binding protein, C4bp.

6.2 Lectin Activities of the Cytokines

Cytokines are a family of soluble proteins that function in both immune- and non-immune systems to mediate cell–cell communication. The classic model of cytokine action is that these proteins bind to cell surface receptors leading to the activation of intracellular signaling cascades. Recent evidence indicates that inhibitors of glycosylation in turn inhibit cytokine-receptor interactions and subsequent signal transduction. Many cytokines have been shown to have specific lectin activity including IL-1, IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-8, and IL-12 as well as TNF-α. As these cytokines do not, as yet, belong to one of the well-defined lectin families, they have been identified as orphan lectins.

Discussion of the lectin-like activities of IL-1, IL-2, and IL-6 serve as interesting examples that includes carbohydrate recognition, receptor activation, and regulation of immune system function. IL-1 constitutes a family of proinflammatory proteins consisting of IL-1α, IL-1β, and IL-1 receptor antagonist, IL-1RA. The carbohydrate structures recognized by IL-1α and IL-1β are quite distinct. IL-1α recognizes a very rare disialylated di-antennary N-glycan whereas, IL-1β interacts with the carbohydrate structures found on neural cell glycolipids of the GM4 type. IL-2 is produced by activated T cells and exhibits biological activities that include additional stimulation of T cells, activation of B cells, and activation of other leukocytes that harbor IL-2 receptors on their surfaces. The

mechanism of IL-2-mediated activation of signal transduction events involves two distinct interactions. One interaction involves binding to the IL-2 receptor itself. The other interaction has been shown to require the presence of N-glycans containing five or six mannose residues with a structure $Man_{5-6}GlcNAc_2$ on the CD3 molecule associated with the T-cell receptor. Interaction of IL-2 with the glycan moiety of CD3 does not require calcium, thus, IL-2 is not a member of the C-type lectin family. IL-6, which functions in hematopoiesis, immunity, and inflammation, exhibits bifunctional binding characteristics like that of IL-2. IL-6 binds to its receptor, which in turn leads to association with an additional protein identified as gp130 as it is a glycoprotein of 130 kDa. As a lectin, IL-6 binds to both O- and N-glycans that are sulfated. Highest affinity is to the HNK-1 epitope (sulfo-GlcNAcGal), which is the terminal glycosylation of a glycoprotein, first identified on the surface of eggs of the frog *Rana temporaria*. Recently, it was demonstrated that the carbohydrate structure on gp130, to which IL-6 binds, is an HNK-1 epitope.

6.3 Sugar Alterations that Affect Immunity

Well over 200 proteins that are expressed on the surfaces of leukocytes are known to be glycosylated. In addition, many proteins involved in the processes of signal transduction that are responsible for the activation and differentiation of B and T cells are O- and N-glycosylated. Adding to the complexity of all these glycosylated proteins is the fact that many individual leukocyte proteins are additionally linked to glycosaminoglycan carbohydrate structures. Because the carbohydrate structures present on leukocyte membrane proteins are nearly equivalent in size to the typical immunoglobulin domain, these structures themselves have the capability to regulate the properties of the cell surface proteins.

As discussed above, animal lectins play critical roles in immunity and disease. The effects of some lectins are inhibitory to cell growth, while other effects promote growth and indeed can even promote tumorigenesis. It would, therefore, seem appropriate for cells to devise mechanisms to regulate the activities of lectins. Many cells activate the expression of lectins in response to a variety of stimuli. However, cellular responses to lectins can also be effected by regulating the events of cell surface presentation of the glycan ligands recognized by the lectins. This latter phenomenon has been best characterized in the cell of the immune system. One of the most important carbohydrate modifications, with respect to leukocyte function, is sialylation. Many of the ligand-receptor interactions discussed above are regulated by the presence or absence of sialic acid residues. The siglecs and selectins require sialylation of their respective ligands in order to bind. In contrast, the binding of many galectins is inhibited by the presence of sialic acid.

Many changes in glycosylation occur during the course of T-cell differentiation as a consequence of changes in the expression of numerous glycosyltransferases and glycosidases. One important glycosylation related to T-cells differentiation is an increase in the level of sialylation. Differences in sialylated structures also distinguish different subsets of T cells from one another. When activated T cells convert to memory T cells, the level of sialylation decreases. Similarly, $CD8^+$ T cells have much less sialic acid on their surfaces than do $CD4^+$ cells. As expected from these observations, the differentiation of T

cells leads to changes in the expression of glycosyltransferases and glycosidases. The glycosidase, sialidase (Neu-1) is induced following stimulation of T cells, whereas, the O-glycan sialyltransferase, ST3Gal-I is induced as T cells mature.

A clear demonstration of the necessity for specific types of glycosylation in the control of immune responses stems from studies with transgenic ''knockout'' mice. Murine *N*-acetylglucosaminyltransferase V (MGAT5) catalyzes the addition of *N*-acetylglucosamine to α6-linked mannose residues of tri- and tetraantennary branched N-glycans. Mice lacking Mgat5 exhibit an exaggerated cellular-immune response to antigen presentation and develop glomerulonephritis, which is characteristic of autoimmune syndromes. These effects are the result of an increase in T-cell receptor (TCR) clustering on the cell surface. The increased clustering leads to a reduced requirement for ligand interaction as evidenced *in vitro* by enhanced TCR signaling with reduced amounts of anti-CD3 antibodies, relative to control cells. It is likely that the *in vivo* response is due to enhanced recruitment of the TCR to antigen-MHC complexes. An additional experiment is aimed at discerning the function of a specific glycosidase, α-mannosidase II (MII) in immune responses. MII is required to remove terminal mannose residues during the conversion of high-mannose type glycans to the complex type. Mice deficient in this enzyme were shown to develop dyserythropoietic anemia (a deficiency in cells of the erythroid lineage of hematopoietic cells), an autoimmune disorder characteristic of immune complex glomerulonephritis (similar to that observed in MGAT5$^{-/-}$ mice) and have antinuclear antibodies similar to those observed in persons with systemic lupus erythematosus.

7
Clinical Significances of Glycoproteins

7.1
Degradation Defects of GlcNAc-Asn Glycoproteins

The proper degradation of glycoproteins has important medical relevance. Degradation of glycoproteins occurs within the lysosomes and requires specific lysosomal hydrolases of the glycosidase family. Exoglycosidases remove sugars sequentially from the nonreducing end and exhibit restricted substrate specificities. In contrast, endoglycosidases cleave carbohydrate linkages from within and exhibit broader substrate specificities.

Several inherited disorders involving the abnormal storage of glycoprotein degradation products have been identified in humans (Table 4). These disorders result from defects in the genes encoding specific glycosidases, leading to incomplete degradation and subsequent overaccumulation of partially degraded glycoproteins. As a general class, such disorders are known as lysosomal storage diseases and include the diseases known as mucolipidoses that result from incomplete degradation of the carbohydrate portions of glycolipids whose structures are the same as those found on glycoproteins.

Aspartylglucosaminuria (AGU) results from a deficiency in the lysosomal glycosidase, *N*-aspartyl-β-glycosaminidase (AGA) that is responsible for hydrolyzing the GlcNAc-β-Asn bond of glycoproteins. Glycoproteins are completely degraded within the lysosome prior to GlcNAC-β-Asn attack by AGA. The enzyme catalyzes bond hydrolysis independent of the complexity of the associated carbohydrate structure. Owing to the defect, glycoasparagines, primarily *N*-acetylglucosaminyl-asparagine,

Tab. 4 Disorders of glycoprotein degradation.

Disease	*Enzyme defect*	*Gene name*	*Location*
Aspartylglycosaminuria	*N*-aspartyl-β-glycosaminidase	*AGA*	4q32-q33
α-Mannosidosis	α-mannosidase	*MANB*	19p13.3-q12
β-Mannosidosis	β-mannosidase	*MANBA*	4q22-q25
α-Fucosidosis	α-fucosidase	*FUCA*	1p34
Galacotosialidosis	Neuraminidase and β-galactosidase-2 deficiency secondary to protective protein/cathepsin A (PPCA) defects	*PPCA (PPGB)*	20q13.1
Sialidosis (Mucolipidosis I)	Neuraminidase (sialidase)	*NEU1*	6p21.3
Schindler disease	α-*N*-acetylgalactosaminidase	*NAGA*	22q11
G_{M1} Gangliosidosis	β-galactosidase-1	*GLB1*	3p21.33
G_{M2} Gangliosidosis (Sandhoff disease)	hexosaminidase B	*HEXB*	5q13
Mucolipidosis II: I-cell disease and Mucolipidosis III Pseudo-Hurler	*N*-acetylglucosamine-1-phosphotransferase	*GNPTA*	4q21-q23

accumulate in lysosomes leading to cell death. The defect results in a slow progressive global delay in psychomotor development in AGU patients. A delay in speech, accompanied with clumsiness, is often preceded by recurrent upper respiratory infections. Patients will only attain the developmental capacity of a 5 to 6-year-old with a progression to severe mental retardation in adulthood. Several mutations in the AGA gene have been identified in AGU patients, spanning insertions, deletions, and point mutations.

Human α-mannosidosis comprises disorders that are associated with abnormal levels and excretion of mannose-rich oligosaccharides. The infantile form (type I), with onset occurring in the first 12 months after birth, causes rapid progressive mental retardation, hepatosplenomegaly, and severe skeletal abnormalities. Afflicted individuals usually die between 3 and 12 years of age. The juvenile-adult form (type II), with onset between 1 and 4 years of age, is less severe with milder symptoms and slower progression. Patients also suffer recurrent infections that may be related to resultant defects in leukocyte chemotaxis. These disorders result from deficiencies in the lysosomal form of the enzyme, α-mannosidase. This enzyme hydrolyses Man-α1,3-Man and Man-α1,6-Man linkages.

Human β-mannosidosis is associated with increased storage and excretion of Man-β1,4-GlcNAc caused by a deficiency in β-mannosidase activity. The enzyme catalyzes the hydrolysis of Man-β1,4-GlcNAc linkages, hence the accumulation of these structures in its absence. Like α-mannosidosis patients, patients lacking β-mannosidase exhibit symptoms with a range of severities. The most frequent symptoms are respiratory infections, hearing loss with associated speech impairment, and mental retardation.

Fucosidosis is caused by a deficiency in the lysosomal hydrolase α-fucosidase. Originally, two classifications of fucosidosis were defined. Type I was the more

severe with infantile onset and type II was the milder form. However, it has become apparent that individuals suffering from fucosidosis exhibit a continuum of symptoms with a wide spectrum of severity. The most severely afflicted individuals have psychomotor retardation, skeletal abnormalities, coarse facial features, and growth retardation. The enzyme defect results in the increased accumulation and excretion of a wide variety of fucose-containing glycoproteins, glycolipids, and oligosaccharides. There are multiple forms of α-fucosidase, all of which have a common subunit encoded by the *FUCA1* gene. At least 23 different mutations in the *FUCA1* gene have been identified in fucosidosis patients.

Sialidosis is a disorder that results from a deficiency in the neuraminidase (sialidase) responsible for cleaving terminal α2,3- and α2,6-sialyl linkages present in oligosaccharides and glycoproteins. Type I sialidosis is the milder of the two forms of the disease. Symptoms are generally benign in type I patients with the most notable sign being the presence of a ''cherry-red spot'' in the fundus of the eyes. Indeed, type I sialidosis is commonly referred to as ''cherry-red spot-myoclonus'' syndrome. Type II sialidosis can be divided into infantile and juvenile forms. Type II individuals suffer from heptosplenomegaly, proteinuria, hydrops, skeletal abnormalities, and coarse facial features. The primary accumulating structures in type I sialidosis are sialylated mono-, di-, and triantennary N-glycosidic *N*-acetyllactosamine oligosaccharides harboring Man-β1,4-GlcNAc at the reducing end.

Neuraminidase (the enzyme deficient in sialidosis) is just one enzyme of a multienzyme complex that includes neuraminidase, β-galactosidase-2, and a protective protein/cathepsin A (PPCA). PPCA has some sequence similarities to carboxypeptidase and deamidase. A disorder that is related to sialidosis, identified as galactosialidosis, is caused by deficiencies in both neuraminidase and β-galactosidase-2 that are secondary to defects in PPCA. Patients afflicted with galactosialidosis have coarse facial features, cherry-red spots, foam cells in the marrow, vacuolated lymphocytes, and vertebral defects. There are three phenotypic variants of galactosialidosis. The early infantile form is associated with hydrops, visceromegaly, edema, skeletal dysplasia, and early death. The late infantile form results in growth retardation, hepatosplenomegaly, and heart abnormalities. The juvenile/adult form causes angiokeratoma, mental retardation, ataxia, and neurologic deterioration. Numerous different sialylated mono-, di-, tri-, and tetraantennary oligosaccharides accumulate in the lysosomes and are excreted into the body fluids. When the PPCA gene was knocked out in transgenic mice, the animals developed a disorder with striking similarities to the severe-form human galactosialidosis strongly implicating that defects in this gene are the cause of galactosialidosis.

Indicative of the overlap in diseases associated with defects in the lysosomal degradation of both lipid and protein structures harboring similar oligosaccharide moieties are G_{M1} gangliosidosis, G_{M2} gangliosidosis, Schindler disease, and mucolipidosis II and III. These diseases are considered within the context of the family of disorders referred to as lysosomal storage or glycosphingolipid storage diseases. Because the enzymes whose deficiencies lead to these diseases are responsible for the degradation of similar carbohydrate structures on glycolipids and glycoproteins, they can be considered in

a discussion of either topic. Because the two gangliosidotic diseases are more appropriately discussed in the context of glycolipid degradation defects, they will not be discussed here. A brief account of mucolipidosis II (I-cell disease) and mucolipidosis III (pseudo-Hurler polydystrophy) was given earlier.

Schindler disease (often classified as a glycosphingolipid storage disease) is caused by a deficiency in the lysosomal hydrolase α-*N*-acetylgalactosaminidase. This enzyme was formerly called α-galactosidase B. Owing to the enzyme defect sialylated and asialoglycopeptides with terminal α-*N*-acetylgalactosaminyl residues accumulate in the lysosomes. In addition, glycolipids and oligosaccharides harboring terminal α-*N*-acetylgalactosaminyl residues also accumulate. There are three forms of Schindler disease. Type I individuals appear normal for their first 9 to 12 months then a developmental delay sets in followed by increasing neurologic impairment and profound psychomotor retardation. The type II disease is an adult onset disorder characterized by mild intellectual impairment and angiokeratoma. Type III Schindler comprises an intermediate and a variable form whose symptoms range from speech and language delay with autistic presentation to seizures and moderate psychomotor retardation.

7.2 Congenital Disorders of Glycosylation, CDG

Congenital disorders of glycosylation (CDGs) represent a constellation of diseases that result from defects in the N-linked glycosylation pathway. To date, there are 10 CDGs that have been classified (Table 5) and in 9 of these the enzyme defect(s) has been identified and characterized. These diseases are clustered into two broad categories. Group I CDG diseases are defined by alterations/deficiencies in the synthesis and/or transfer of the Dol-PP-oligosaccharide precursor to asparagine residues in substrate proteins. Group II CDG diseases are defined as those that result from defects in subsequent N-linked glycan processing. Each of the 10 CDGs present in the clinic with a similar constellation of symptoms including hypotonia and hepatomegaly. All but CDG-Ib result in psychomotor retardation of varying degrees. Because these disorders all result from defective N-glycosylation, individuals who present with several of the typical clinical symptoms can be tested for protein

Tab. 5 Congenital disorders in glycosylation.

CDG type	*Defect*	*Gene name*	*Location*
Ia	Phosphomannomutase 2	*PMM2*	16p13.3-p13.2
Ib	Phosphomannose isomerase	*PMI*	15q22-qter
Ic	$Man_9GlcNAc_2$-PP-Dol glucosyltransferase	*ALG6*	1p22.3
Id	$Man_5GlcNAc_2$-PP-Dol mannosyltransferase	*ALG3*	3
Ie	Dol-P-Man synthase 1	*DPM1*	20q13
If	Dol-P-Man utilization defect 1	*MPDU1*	17p12-13
Ix	Like Ia but normal *PMM2* and *PMI*		
IIa	*N*-acetylglucosaminyltransferase II	*MGAT2*	14q21
IIb	Glucosidase I	*GSC1*	2p12-13
IIc (LAD II)	GDP-fucose transporter	*FUCT1*	11

misglycosylation by gel electrophoresis. Commonly, serum transferring is the protein of choice for this analysis. It is important to note that these disorders are only reflective of deficiencies of N-glycosylation and that diseases/disorders are known to result from deficiencies in O-glycosylation, GPI linkage and the biosynthesis of proteoglycans, all of which involve carbohydrate addition and remodeling in the context of a protein backbone.

CDG-Ia is the most commonly occurring CDG, with appearance in individuals of European ancestry being highest. Although there is considerable variability in the clinical phenotypes observed in CDG-Ia patients, there is always some level of psychomotor retardation. In addition, children are ataxic and have skeletal abnormalities consisting of long limbs and short torsos. Owing to defective synthesis of coagulation factors by the liver (primarily factor XI, antithrombin III, protein C and protein S), patients have severe coagulation defects. Adding to the situation is hepatomegaly with consequent liver dysfunction. CDG-Ia results from mutations in phosphomannomutase 2 (PMM2), the enzyme that is required to convert Man-6-P to Man-1-P used in the generation of GDP-Man. Over 60 mutations in PMM2 have been identified that either decrease enzyme activity or stability.

CDG-Ib results from defects in the isomerase (phosphomannose isomerase, PMI) necessary to convert fructose-6-P to Man-6-P. Deficiencies in this enzyme cause loss of plasma proteins via the intestines (protein losing enteropathy, PLE), diarrhea, and cyclical vomiting. Liver dysfunction is caused by hepatomegaly and results in coagulation defects and hypoglycemia. Thankfully, CDG-Ib patients are spared from mental defects. Because free mannose is not found at any appreciable level in foods, dietary supplementation with mannose can ameliorate some of the symptoms of CDG-Ib.

CDG-Ic results from defects in α1,3 glucosyltransferase (ALG6) and eight mutations have been identified in the gene in patients with this disorder. ALG6 catalyzes the addition of the first glucose residue to the *en bloc* oligosaccharide that is subsequently N-linked to proteins. As a consequence of the defective ALG6 enzyme, the oligosaccharide unit is not transferred from dolichol to proteins. Symptoms of CDG-Ic are similar to those of CDG-Ia but much less severe. Patients have frequent seizures and mild psychomotor retardation. Intestinal symptoms of CDG-Ic are markedly exacerbated by intestinal viral infections due to a decline of glycosylated structures (both proteins and proteoglycans) on the basolateral surfaces of intestinal enterocytes.

Few cases of CDG-Id, CDG-Ie, and CDG-If have been reported in the literature. Each of these three disorders are related via enzymes that synthesize or utilize Dol-P-mannose structures. CDG-Id results from deficiencies in Dol-P-Man:Dol-PP-$Man_6GlcNAc_2$ α1,3-mannosyltransferase (α-1,2-Man-T). This enzyme transfers Man from Dol-P-Man to Dol-PP-$Man_5GlcNAc_2$ of the growing *en bloc* oligosaccharide. CDG-Ie results from defects in the catalytic subunit of Dol-P-Man synthase (GDP-Man:Dol-P mannosyltransferase, *DPM*1). Dol-P-Man is required for mannose elongation reactions necessary to produce the *en bloc* oligosaccharide of N-glycans, GPI-anchored proteins, and many other Man-containing glycoconjugates. Patients with CDG-If have defects in an enzyme, MPUD1, required for the utilization of Man-P-Dol and Glc-P-Dol. CDG-Id and CDG-Ie individuals suffer severe neurological impairment including

psychomotor retardation and intractable seizures. Both disorders result in eye abnormalities, optic atrophy in CDG-Id, and cortical blindness in CDG-Ie. Persons with CDG-If have clinical symptoms including hypotonia, frequent seizures, severe psychomotor retardation, and cerebral atrophy. Additionally, these individuals fail to thrive after birth.

CDG-IIa results from loss of the enzyme UDP-GlcNAc:α-6-D-mannosidase β1,2-*N*-acetylglucosaminyltransferase II (GlcNAc-TII), which is encoded by the *MGAT2* gene. The results of this defect are significant loss of complex sialylated structures. Following transfer of the *en bloc* oligosaccharide to asparagine residues, only monosialylated structures are made. Symptoms of CDG-IIa include severe psychomotor retardation, hypotonia, coarse facies, and frequent infections. In experiments in mice, it was found that Mgat2 null animals all died within four weeks after birth and a significant number die *in utero* from gastrointestinal blockage. From these results, it is speculated that the true incidence of human Mgat2 defects may go undetected because of spontaneous fetal abortion or death shortly after birth.

7.2.1 Leukocyte Adhesion Deficiency Syndrome II, LAD II

CDG-IIb is more commonly referred to as leukocyte adhesion deficiency syndrome II (LAD II). LAD II belongs to the class of disorders referred to as *primary immunodeficiency syndromes* as the symptoms of the disease manifest because of defects in leukocyte function. Symptoms of LAD II are characterized by unique facial features, recurrent infections, persistent leukocytosis, defective neutrophil chemotaxis, and severe growth and mental retardation. The genetic defect resulting in LAD II is in the pathway of fucose utilization leading to loss of fucosylated glycans on the cell surface. An additional feature of LAD II is that individuals harbor the rare Bombay (hh) blood type at the ABO locus as well as lack the Lewis blood group antigens (see Fig. 2). The Bombay blood type is characterized by a deficiency in the H (referred to as the O-type), A and B antigens due to loss of the fucose residue. Each of these blood group antigens contains a Fuc-α1,2-Gal modification that is the final carbohydrate addition to these antigens. These fucosylation reactions are catalyzed by α1,2-fucosyltransferase, which is encoded by the *H* and *Se* loci. The defective neutrophil chemotaxis is due to the loss of a selectin ligand on these cells. This ligand is the sialylated Lewis^x antigen, another blood group antigen.

The recurrent infections seen in LAD II patients are the result of the defective neutrophil function. Neutrophils are involved in innate immunity responses to bacterial infection. To carry out their role in host-defense mechanisms, neutrophils must adhere to the surface of the endothelium at the site of inflammation, which is an event mediated by cell surface–adhesion molecules. The selectin family (E-, L-, and P-selectins) of animal lectins are necessary to mediate the initial process of neutrophil adherence to the endothelium. The selectins recognize sialylated fucosylated lactosamines typified by the Lewis^x antigen (see Fig. 2). Once neutrophils adhere and roll along the surface of the endothelium (due to vascular flow), the integrin family of adhesion molecules allow for firm adherence followed by tissue penetration. A related disorder, termed LAD I, is caused by the absence of CD18, which is the β2 subunit of the leukocyte integrin found on the surface of neutrophils and monocytes.

Because there is widespread loss of fucosylated antigens in LAD II patients, each of which can be formed through the actions of several fucosyltransferases, the role of these enzymes in the disease could be ruled out. In addition, normal levels of the α1,2-, α1,3- and α1,4-fucosyltransferases were observed in the serum of LAD II individuals. These observations indicated that the pathways to GDP-fucose synthesis or utilization by the fucosyltransferases in the Golgi must be deficient in LAD II. Fucose can be converted to GDP-fucose by salvage of free fucose (exogenous or derived through glycoconjugate degradation) or by epimerization of GDP-mannose. In order for GDP-fucose to be utilized by Golgi fucosyltransferases it must first be transported into the Golgi from the cytosol where it is synthesized. Examinations of the enzymes involved in the synthesis and transport of GDP-fucose have been undertaken. While the activity of one of the enzymes of GDP-mannose epimerization (GDP-D-mannose 4,6-dehydratase, GMD) has been shown to be reduced in LAD II patients, it has been determined that the major defect causing LAD II is an impairment in the transport of GDP-fucose into the Golgi.

7.3 Exploitation of Host Glycosylation

Many viruses, bacteria, and parasites exploit the presence of cell surface carbohydrates, principally associated with protein, using interaction with them as the means of entry into the cell (Table 6).

Tab. 6 Cell surface glycoproteins that function as receptors or coreceptors for pathogen entry.

Cell surface protein	*Pathogen*
ICAM-1	Rhinoviruses
ICAM-1	Coxsackieviruses
N-CAM	Rabies virus
Dystroglycan	Lymphocytic choriomeningitis virus
Dystroglycan	Lassa fever virus
Dystroglycan	Oliveros and Mobala viruses
Dystroglycan	*Mycobacterium leprae*
Chemokine receptors: CCR1, CCR5, and CXCR4	Poxviruses
CD4	Human immunodeficiency virus
CD46	Human herpes virus 6
CD46	Measles virus
CD55	Coxsackieviruses
CD55	Echoviruses
Pvr	Poliovirus
HveB and C	Herpes simplex viruses 1 and 2
Integrin $\alpha_v\beta_3$	Foot-and-mouth disease virus
Integrin $\alpha_v\beta_5$	Cocksackieviruses
Integrin $\alpha_v\beta_3$ and $\alpha_v\beta_5$	Adenovirus
VLA-2	Echoviruses
Erythrocyte IL-8 receptor (Duffy blood group antigen)	*Plasmodium vivax*
Glycophorin	*Plasmodium falciparum*
Glycophorin	Influenza virus
Lewis^b antigen	*Helicobacter pylori*

Additionally, the surface glycoproteins of many pathogens are necessary for interaction with host cell surface antigens. Several clinically important examples will be presented here.

Human immunodeficiency virus (HIV), the causative agent of acquired immunodeficiency syndrome (AIDS), is a retrovirus that is a member of the family of lentiviruses that cause degenerative diseases. All lentiviruses establish a persistent infection of cells of the macrophage/monocyte lineage. Infective HIV contains a coat surface glycoprotein that is designated gp120. It is interaction of HIV gp120 with the T-cell surface glycoprotein, CD4, that is the major interaction required to initiate the infection process. CD4 is a ligand for major histocompatibility complex (MHC) class II molecules and is a member of the Ig superfamily of proteins. Macrophages and dendritic cells express barely detectable levels of CD4, thus, HIV infection is thought to occur through interactions with other glycoproteins or lectins on the surfaces of these cell types. Indeed, a protein on dendritic cells identified as DC-SIGN, has been demonstrated to have high affinity for gp120. Additionally, it is known that the host proteins are incorporated into HIV virions and consequently aid in HIV attachment to cells. Examples include ICAM-1, which when present in the virion surface allow HIV to attach to cells expressing the ICAM-1 ligand LFA-1 (GPI-anchored protein).

Although CD4 has been clearly demonstrated to be the major receptor for HIV infection, evidence has shown that CD4 alone is insufficient for fusion of virions with cells to which they are attached. Virus entry requires interaction with additional cell surface glycoproteins. These proteins have been termed HIV coreceptors. The strongest coreceptors for HIV infection are proteins that belong to a class of cellular receptors known as the chemokine receptors. Chemokines are chemoattractant proteins having roles in inflammation and immune responses as well as roles in early development. The most potent chemokine receptors involved in HIV entry into cells are CXCR4 and CCR5.

Human herpesvirus 6 (HHV-6) infection occurs in virtually all persons within the first two years of life and persists the entire lifetime. In immunocompromised patients, HHV-6 causes opportunistic infections and is the causative agent of *exanthema subitum*. HHV-6 has been linked to multiple sclerosis and to the progression of AIDS. The cellular receptor for HHV-6 is the cell surface type I glycoprotein, CD46.

Dystroglycan (DG) is a component of the dystrophin–glycoprotein complex. It is a laminin receptor encoded by a single gene and cleaved by postranslational processing into two proteins, peripheral membrane α-DG, and transmembrane β-DG. Alpha-DG interacts with laminin-2 in the basal lamina and β-DG binds to dystrophin-containing cytoskeletal proteins in muscle and peripheral nerves. DG is involved in agrin- and laminin-induced acetylcholine receptor clustering at neuromuscular junctions, morphogenesis, early development, and the pathogenesis of muscular dystrophies. Evidence has demonstrated that α-DG present on Schwann cell membranes is the receptor for *Mycobacterium leprae* and also serves as the receptor for the arenavirus class of pathogens. Arenaviruses cause hemorrhagic fever in humans. Lymphocytic choriomeningitis virus (LCMV), Lassa fever virus (LFV), Oliveros and Mobala (all members of the arenavirus family) all bind to α-DG. The specificity of this interaction was demonstrated by the resistance to LCMV infection of cells harboring a null mutation in DG.

The MN blood group system is a well-characterized set of erythrocyte surface antigens that represent the variable carbohydrate modifications of the transmembrane glycoprotein, glycophorin. Glycophorin is the cellular receptor for influenza virus as well as the receptor for erythrocyte invasion by the malarial parasite *P. falciparum*. The related malarial parasite, *P. vivax*, interacts with the erythrocyte chemokine receptor for the cytokine IL-8 (which is in fact a chemokine). This erythrocyte surface glycoprotein is also known as the Duffy blood group antigen.

*H. pylori*is a gram-negative bacterium that is found in the stomachs of over 50% of the human population. However, even with this wide distribution, significant pathological consequences to infection are only seen in a subpopulation. In this subpopulation, the bacterium is responsible for chronic active gastritis and gastric and duodenal ulcers and has also been shown to be the causative agent for one of the most common forms of cancer in humans, gastric adenocarcinoma. Indeed, in 1994, *H. pylori* was designated as a human carcinogen. *H. pylori* resides mainly in the mucous layer of colonized individuals. The bacterium can, however, directly interact with gastric epithelial cells expressing the Lewis^b (Le^b) blood group antigen on their surfaces. The Lewis^b antigen is very similar to the B antigen (see Fig. 2) except that the terminal residue in the Lewis^b carbohydrate structure is Fuc, whereas on the B antigen it is Gal. Although binding to the Lewis^b antigen allows *H. pylori* to directly interact with the gastric epithelium, it is not this interaction that is important in the clinical course of colonization. Progression in the development of gastric cancer involves loss of stomach parietal and pepsinogen-producing epithelial cells. The loss of these cells types is associated with an increase in the exposure of progenitor cells and in the synthesis of sialylated glycans. *H. pylori* also binds to sialic acid containing glycans with the terminal structure, Sia-α2,3-Gal-β. This is the same structure present in the sialylated Lewis^x antigen (see Fig. 2). Persistent colonization of *H. pylori* at sites with increased progenitor cell proliferation is conducive to the further transformation of these cells.

8 Medical Applications of Carbohydrates and Glycoproteins

Given that several biotechnology and pharmaceutical companies are testing the utility of certain carbohydrate-related compounds in the treatment of disease (Table 7 here), it is clear that oral delivery of sugars has benefits far beyond simply serving as sweeteners. In addition to using sugars as therapeutics, the use of inhibitors of carbohydrate recognition and glycosylation inhibitory compounds has clinical significance for treatments ranging from cancer to diabetes.

The congenital disorder in glycosylation type Ib (CDG-Ib) is caused by a deficiency in the ability of cells to convert fructose to mannose (see Sect. 7.2). As indicated earlier, the administration of mannose to afflicted individuals has shown striking promise in the amelioration of the severe intestinal symptoms of this disease. Leukocyte adhesion deficiency II (LAD II) results from a defect in the intracellular transport of GDP-fucose into the Golgi (see Sect. 7.2.1). Oral supplementation of fucose has been shown to induce the expression of fucosylated selectin ligands on neutrophils and core fucosylation of serum glycoproteins. The result of these supplementations showed

Tab. 7 Carbohydrate compounds or inhibitors in the clinic.

Company	*Carbohydrate/inhibitor*	*Clinical indication*
Austin Research Inst.	Mannan/mucin formulation	Breast cancer
Biomira	Sialyl Tn antigen conjugate	Metastatic cancer
GLYCODesign	Swainsonine analog	Renal cell carcinoma
Oxford glycosciences	Imino sugar analog	Gaucher's disease
Progen Industries	Sulfated oligosaccharide	Cancer
Progenics	G_{M2}/G_{D2}/KLH conjugate	Cancer
Progenics	G_{D2}/KLH conjugate	Melanoma
SafeScience	Pectin-based oligosaccharide	Cancer
Synsorb Biotech	Oligosaccharide conjugate	*Clostridium difficile* infection
Synsorb Biotech	Oligosaccharide conjugate	*Escherichia coli* O157:H7 infection

that neutrophil counts returned to normal reducing infection in rats and fever as well as an improvement in psychomotor capabilities.

The selectin class of lectins is critically important in the normal function of leukocytes in processes of inflammation. Studies in mice showed that blocking the targets of the selectins can reduce inflammatory responses to blood vessel damage. Blocking L-selectin recognition of the $Lewis^x$ antigen showed particular promise. However, human clinical trials have been disappointing. Currently, the drug company, Wyeth, is testing a P-selectin inhibitor in the treatment of ischemic reperfusion injury with initial success. Inhibition of P-selectin binding to its ligand may also hold promise as an anticancer regimen. Metastatic cancer cells adhere to P-selectin on platelets, which in turn protect them from being recognized by the immune system.

Golgi α-mannosidase II is a key enzyme in the processing of N-linked glycoproteins and has been shown to be a potential target for the development of antiviral and anticancer therapies. The glycosylation inhibitors swainsonine and deoxymannojirimycin block the action of α-mannosidase II. A deoxymannojirimicin analog, *N*-nonyldeoxynojirimicin (NN-DNJ) has been shown to block the infectivity of human hepatitis B and C viruses. The ER located α-mannosidase I is responsible for trimming of a single mannose residue and as a consequence acts as a signal to target misfolded glycoproteins for degradation by the proteasome. The potent α-mannosidase I inhibitors, kifunensine and 1-deoxymannojirimycin, may prove useful in the design of novel inhibitors that prevent degradation of misfolded proteins in genetic diseases.

The action of the intestinal enzyme, α-glucosidase, is to aid in the digestion and subsequent absorption of dietary saccharides. Two sugar-related α-glucosidase inhibitors, BAY m-1099 (Miglitol) and BAY g-5421 (Acarbose), have been targeted in the clinic as antidiabetic drugs. The action of these inhibitors prevents complete digestion of dietary carbohydrate, thus reducing glucose uptake. Although targeted for the same condition, the effects of these inhibitors are somewhat different owing to the fact that only Miglitol shows appreciable absorption into the blood stream. A secondary benefit to the uptake of Miglitol is that studies have shown that not only does the drug impair glucose absorption but it also enhances insulin

responsiveness and decreases glucagon-induced glycogen breakdown.

Keywords

Sex Determination
The process by which the sexually undifferentiated embryo is induced to become male or female.

Gonad
The sex gland, testis or ovary, which produces the haploid gametes, and secretes the hormones that determine appearance of the secondary sex traits.

Testis-determining Gene
The Y-chromosomal gene that governs male sex determination.

Sex Reversal
Any of several conditions in which gonadal sex is at variance with chromosomal sex or body sex.

The manner in which the indifferent embryonic gonad is induced to become testis or ovary is a prime question in developmental biology, and may have more general relevance for ontogeny as a whole. Identification of a pathway of sex-determining genes and their products will provide useful insights into the nature of sex differentiation and the various syndromes of abnormal gonadal development, as well as new approaches to the diagnosis and study of these conditions. Differentiation of the gonad is the key event leading to development of the sex phenotype. In males, this event is governed by the Y chromosome testis-determining gene, and other, recently discovered, X-linked and autosomal genes. In females, in the absence of the Y chromosome, alternative pathways are set in motion.

1 Introduction

In human embryos, as in mammalian embryos in general, there are two sets of genital ducts: (1) the Wolffian ducts, which give rise to the epididymides, vasa deferentia, and seminal vesicles, and (2) the Müllerian ducts which give rise to the fallopian tubes, uterus, and cephalad vagina. In males, the Wolffian ducts develop and the Müllerian ducts regress, and in females, the Müllerian ducts develop and the Wolffian ducts regress. Because the internal male ducts appear and the Müllerian ducts regress just after differentiation of the testis, the question was asked whether the testis might play some role in those events.

In the early 1940s, a young French scientist named Alfred Jost set out to answer that question. And just after World War II, he described a series of experiments that mark a turning point in the biology of sex differentiation. When Jost castrated rabbit fetuses at day 19 *in utero*, they went on to develop as females regardless of the sex of the gonad that he had removed. He inferred that the inherent tendency of the mammalian embryo is to develop as a female, and that maleness is imposed by the testis against that tendency.

To clarify the role of the male gonad in the growth of the male genital ducts, Jost grafted a fetal testis next to a fetal ovary in a 20-day rabbit embryo. On inspecting the embryo at 28 days (just before birth), he noted inhibition of the Müllerian duct on the side of the grafted testis and ''partial maintenance'' of the Wolffian duct. When a small crystal of testosterone propionate was substituted for the implanted testis, he again noted the maintenance of the Wolffian duct, but this time there was no inhibition of the Müllerian duct.

It was thus demonstrated that the fetal testis produces two factors – one that induces development of the Wolffian derivatives, and one that blocks development of the Müllerian derivatives. Today, we know that the former is testosterone and the latter is the anti-Müllerian hormone (AMH) (also called *Müllerian inhibiting substance* or *MIS*). In normal male fetuses, some of the testosterone is converted to the more potent androgen, dihydrotesterone (DHT), which mediates the timely appearance of the male external genitalia.

On the basis of his observations, Jost summarized the fundamental mechanism of mammalian sex differentiation in this paradigm. *Sex differentiation involves a series of orderly processes: establishment of genetic sex at conception, translation of genetic sex into gonadal sex, and translation of gonadal sex into body sex.*

The gene that sets these processes in motion is located on the Y chromosome (Fig. 1). In the presence of the Y, the gonad becomes a testis; the testis secretes testosterone and AMH, and further development is male. In the absence of the Y, the gonad becomes an ovary; testosterone and AMH are not secreted, and further development is female.

In this article, we describe the search for the Y-situated testis-determining gene, with emphasis on the molecular methods leading to its isolation and characterization in 1990. We continue with a discussion of autosomal and X-linked sex-determining genes, and we conclude with a survey of the extraordinary conditions that can result when any of the sex-determining genes are mutated or expressed abnormally.

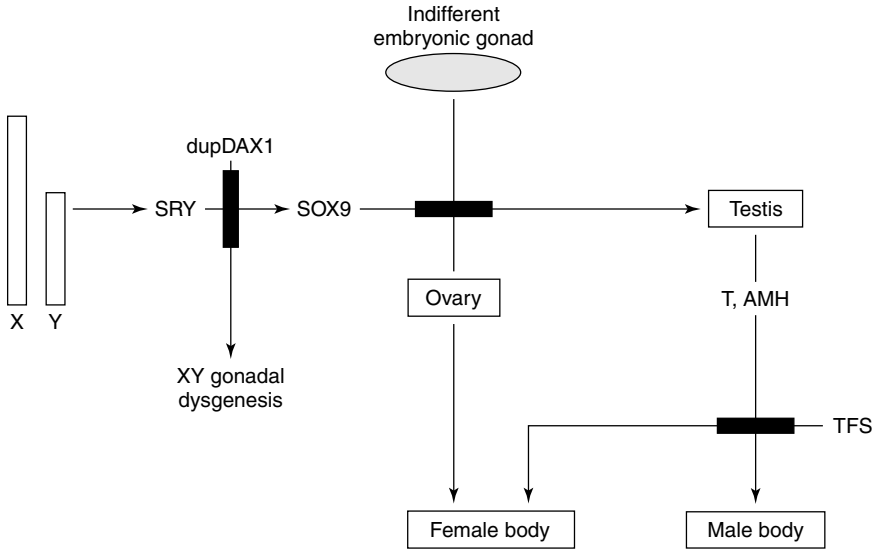

Fig. 1 Sex determination in the human. In XX embryos, the indifferent embryonic gonad becomes an ovary and the body develops along female lines. In the presence of the Y-chromosome-situated *SRY* gene, the indifferent gonad becomes a testis. The testis secretes testosterone (T), which induces the wolffian ducts, and anti-Müllerian hormone (AMH), which blocks formation of the Müllerian ducts; in this case, the body develops along male lines. Response to testosterone and its metabolite, dihydrotestosterone (DHT), is mediated by the androgen receptor, encoded by a gene on the X chromosome. When this gene is mutated or absent, the embryo develops as a female despite the presence of Y chromosome and testes. The resulting condition is called *testicular feminization syndrome* (TFS). Duplication of another X-linked gene, *DAX1*, blocks the testis-determining function of *SRY*, and the result is XY gonadal dysgenesis (see Fig. 7). The *SOX9* gene, on chromosome 17, is a downstream target of *SRY*. Duplication of *SOX9* in the absence of the Y chromosome causes development of XX testes (not indicated in the figure).

2
Search for the Testis-determining Gene

2.1
The H-Y Antigen Gene (*HYA*)

It is a dictum of biology that genes of fundamental significance are conserved and thus relatively unchanged from species to species. On this basis, a number of genes have been proposed as candidates for the Y-linked testis-determining gene. One such candidate was the gene for the male-specific H-Y antigen.

In inbred strains of the mouse, male grafts are rejected by female recipients, whereas grafts exchanged among the other sex combinations are accepted. This happens because male tissues contain a cell-surface antigen, H-Y, encoded by a Y-chromosomal gene that has no counterpart in females. When challenged with male grafts, female mice also produce antibodies that can react with male cells from a broad spectrum of mammalian species. In view of this phylogenetic stability, it was proposed in 1975 that H-Y antigen was the product of the testis-determining gene.

To test the idea, H-Y antigen was studied in cases of abnormal sex differentiation – especially in cases of sex reversal

such as XX male syndrome, XY gonadal dysgenesis, and true hermaphroditism. If H-Y were the product of the testis-determining gene, it should always be present in association with testicular tissue, regardless of chromosomal sex or body sex. For nearly a decade, the proposal was supported experimentally, but in 1984, a line of XX male mice lacking the H-Y antigen was discovered, and the search for the testis-determining gene was redirected.

[In 1995, the gene for human H-Y antigen (*HYA*) was mapped to the long arm of the Y chromosome, and the gene for mouse H-Y *(Hya)*, to the *short* arm of the mouse Y, between *Zfy-1* and *Zfy-2* (see Sect. 2.3). But the function of H-Y remains to be ascertained.]

2.2
Bkm Satellite DNA

A satellite is a repetitive sequence of chromosomal DNA in which the nucleotide pairs G : C and A : T are represented unequally. This gives the satellite a density that is different from the density of sequences in which the nucleotide pairs are equally represented (Fig. 2). And this enables geneticists to identify and isolate satellite DNA from the main body of genomic DNA by centrifugation along a density gradient. A common repetitive sequence in satellite DNA is the tetranucleotide, GATA, which is conserved in evolution.

Satellites occur in the heterochromatic regions of the chromosomes, which are in general genetically inert. They are common, for example, in the long arm of human Y chromosome. In snakes, the female is the heterogametic sex – that is, the female carries the ZW chromosome pair, corresponding to the XY pair in mammals. Like the mammalian Y, the snake W contains heterochromatic regions rich in satellites.

In fact, several satellites have been isolated from the W chromosome of the poisonous snake, *Bungarus fasciata*, the banded krait. One such

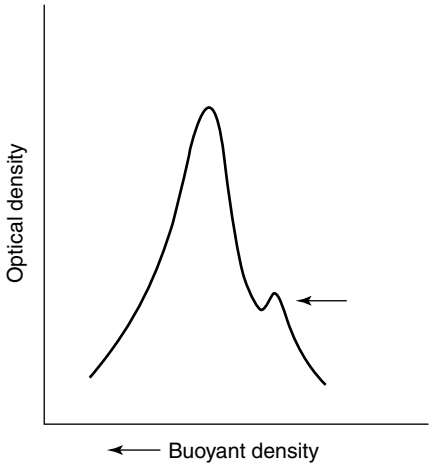

Fig. 2 Satellite DNA. The buoyant density of double-stranded DNA – determined by centrifugation through a cesium chloride density gradient – is a function of G–C content. The larger peak above includes about 90% of the genome, centered about a value of 1.70 g cm^{-3} corresponding to a mean G–C content of 42%, which is typical of mammals. The smaller peak (arrow), representing about 10% of the genome, is a satellite DNA with a G–C content of some 30% and a buoyant density of 1.69 g cm^{-3}. Satellites may have densities greater or smaller than the density of the main band. (From Wachtel, S.S., Tiersch, T.R. (1994) The Search for the Male-determining Gene, in: Wachtel, S.S. (Ed.) *Molecular Genetics of Sex Determination*, Academic Press, San Diego, CA, pp. 1–22).

satellite – consisting mostly of GATA repeats – was called *banded krait minor satellite DNA*, or *Bkm*, for short. The *Bkm* repeat sequence was found to be a regular component of the W chromosome in a wide variety of ophidian species.

Bkm was not limited to snakes. It was found in other reptiles, and in birds, mammals, and even insects. Although present in autosomes, and hence in both sexes of the mouse, the GATA repeats were concentrated in the sex-determining region of the Y chromosome. This prompted researchers to ask whether *Bkm* might be involved in mammalian sex determination.

In addressing that question, Lalji Singh and Kenneth Jones of the University of Edinburgh used *Bkm* as a probe for Y chromosome sequences in XX*Sxr* males. The *Sxr* ''mutation'' causes XX embryos of the mouse to develop as phenotypic males with small sterile testes. It is transmitted by fertile XY*Sxr* carrier males to half their XX offspring (Sect. 5.1.2). In 1982, it was generally assumed that male development in XX*Sxr* mice was due to a mutant autosomal gene, or alternatively, due to a submicroscopic Y-autosome translocation. But Singh and Jones found a concentration of *Bkm* in one of the X chromosomes of the sex-reversed males, similar to the cluster that is normally found in the Y. They showed that *Sxr* sex reversal is due to a nonreciprocal recurrent Y-X translocation of the sex-determining gene in the germ line of the carrier male. Because the translocation was so small as to have escaped detection by cytogenetic analysis, *Bkm* and the testis-determining gene appeared to be closely linked, and perhaps identical.

This was a pivotal work, because it resolved a fundamental mechanism of sex reversal in the mouse, and led the way to similar studies in XX males of the human (see Sect. 5.1.1). Yet, later studies showed that *Bkm* was not likely to be the testis-determining gene in man, because GATA sequences were present throughout the human genome and there were no concentrations of *Bkm* in the human Y. Once again the search for the testis-determining gene was redirected, but with the work on *Bkm*, the study of vertebrate sex determination had passed from the purview of immunogenetics into the realm of molecular biology.

2.3
Zinc Finger Y Gene (*ZFY*)

With respect to sex-reversed conditions such as XX male syndrome and XX true hermaphroditism (Sect. 5), the question arises why one XX embryo should develop unambiguous testes (an XX male), and another, ovaries and testes in some combination – for example, ovotestes or ovaries and testes (an XX true hermaphrodite). In 1966, Malcom Ferguson-Smith proposed that both conditions could arise as a result of X-Y translocation involving transfer of the testis-determining gene from the Y chromosome to the X (Fig. 3).

According to that proposal, the sex of an XX embryo carrying the X;Y translocation would depend on variable patterns of X chromosome inactivation *(lyonization)*. If the X;Y translocation chromosome (the one bearing the testis-determining gene) were preferentially activated in the developing gonads, the embryo would become a male. If it were activated in one gonad and inactivated in the other, the embryo would become a true hermaphrodite with testis versus ovary. An ovotestis would develop if the X;Y chromosome were activated in one part and inactivated in another part of a

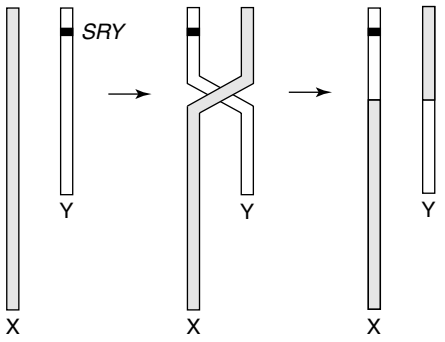

Fig. 3 Translocation of the male-determining gene resulting from crossover of the X and Y chromosomes during meiosis. If the translocated fragment contains the testis-determining gene (*SRY*), and if an egg is fertilized by a sperm cell carrying the affected X chromosome, the resultant embryo becomes an XX male. X;Y translocations have been identified in about 70% of human XX males.

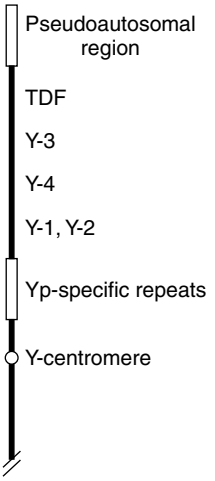

Fig. 4 Deletion map of the Y chromosome. Order of hypothetical Y-fragments based on their frequency of occurrence in XX males; see text.

single gonad – and so on. In support of the proposal of Ferguson-Smith, X-Y translocations have been observed in about 70% of XX males that have been studied.

The fact that these translocations involved unequal amounts of Y chromosome material enabled construction of Y chromosome deletion maps. The closer to the testis-determining gene a particular fragment is, the more likely that it will be included in an X;Y translocation. Thus, translocated fragments closer to the testis-determining gene should be found in a greater proportion of XX males than should fragments further from that gene.

After the enrichment and separation of populations of Y chromosomes in a flow cytometer, it is possible to digest the DNA to obtain Y-fragments of variable size. These can be used as probes to detect corresponding Y-fragments in XX males. Some of the fragments could be found more often than others in DNA from different XX males. Consider four hypothetical fragments: Y-1, Y-2, Y-3, and Y-4. Say, for example, that Y-1 and Y-2 are present in about half of the XX males surveyed, whereas Y-4 is present in three-fourths and Y-3 is present in all. It could be inferred that among these sequences, Y-3 is closest to the testis-determining gene, Y-4 is next in line, and Y-1 and Y-2 are the farthest. When sequences are localized in this way, a deletion map can be constructed (Fig. 4).

In 1987, David Page and colleagues at the Whitehead Institute used this method to produce a map of the short arm of the human Y chromosome (Yp), containing 13 deletion intervals. One of the intervals – denoted 1A2 and consisting of only 140 kb (about 0.2% of the Y chromosome) – was present in an XX male who possessed only 300 kb of Y-DNA. It was absent in a woman with a Y,22 translocation who possessed all but 160 kb of the Y. Because she was a woman, the testis-determining gene (called *TDF* in those days) was most probably situated in the part of the Y that she lacked. It was inferred that interval 1A2 contains "an essential portion if not all" of *TDF*, and that *TDF* could be further localized by looking for highly conserved sequences within 1A2.

A series of Y-probes was developed, representing collectively the entire 1A2 deletion interval. The probes were tested against samples of DNA from a wide variety of species in Southern blots *(Noah's Ark blots)*. Many of the probes identified corresponding fragments from humans and great apes, but under conditions of greater stringency, they did not hybridize with DNA from more distant species.

One probe, however, designated pDP1007, and consisting of a 1.3 kb *Hind*III fragment, was hybridized with a single-copy sequence in males from every mammalian species tested, including gorilla, rhesus monkey, owl monkey, rabbit, dog, goat, horse, and cattle. This indicated that a fragment corresponding to pDP1007 was present in the Y chromosome of each of these species. In addition to the Y-specific fragment, pDP1007 identified a fragment that was present in males and females. Because the hybridization signal of the second fragment was stronger (more dense) in females than it was in males, that fragment was assumed to be on the X chromosome.

Next, the DNA sequence of the Y-fragment was determined, and the order of amino acids in the corresponding protein was derived. When compared to other amino acid sequences, the sequence of the protein encoded by pDP1007 was found to resemble closely the sequences of proteins with tandemly repeated "finger" domains. Finger proteins are regulatory. They are known to bind DNA and thereby regulate transcription–conversion of the DNA sequence into a messenger RNA sequence.

Because pDP1007 recognized a sequence in a tiny fragment of Y-DNA present in an XX male and absent in an "XY" female, because the pDP1007 sequence was phylogenetically conserved and male-specific, and because the corresponding protein was likely to govern transcription, it was suggested that the protein identified by pDP1007 was the product of the testis-determining gene, *TDF*. According to that suggestion, the protein might bind DNA in a sequence-specific manner, and thereby regulate transcription of another gene in the pathway leading to testicular differentiation.

The gene recognized by pDP1007 was called *ZFY* (for *zinc finger Y*) because zinc ions establish complexes with its finger domains reminiscent of the complexes formed between iron porphyrin and the subunits of hemoglobin. The X-linked homolog was called *ZFX*.

Once *ZFY* was described, geneticists began to look for similar genes in species more distant than those already studied. When the pDP1007 probe was used to search for *ZFY* sequences in reptiles, positive hybridization was obtained, but the results were the same in male and female. Was there *expression* of

ZFY in both sexes? To answer that question, the pDP1007 probe was used to screen RNA extracted from embryos of the snapping turtle, in which sex is determined by the temperature of incubation (embryos that develop at higher temperatures become females; those that develop at lower temperatures become males). The probe hybridized with RNA from embryos maintained at female-determining *and* at male-determining temperatures, indicating that *ZFY* or a *ZFY*-like molecule is transcribed in both sexes in that species.

In the mouse, two *ZFY* genes were identified on the Y chromosome *(Zfy-1* and *Zfy-2)*, and one on the X *(Zfx)*. The *Zfy-1* and *Zfy-2* genes were both found in sex-reversed XX*Sxr* male mice but only *Zfy-1* was found in XXSxr^b males. Because XXSxr^b mice carry a deleted, if still male-determining, *Sxr* region, it could be inferred that *Zfy-2* is not required for differentiation of the mouse testis. Both genes were expressed during development of the mouse embryonic testis, but neither was expressed in mutant embryonic testes lacking germ cells. These findings seemed to imply that neither *Zfy-1* nor *Zfy-2* played a critical role in the development of the mouse testis, but they did not rule out a possible role for *Zfy-1* in the ontogeny of the male germ cell.

In marsupials, the pDP1007 probe hybridized with DNA from males and females, and *in situ* hybridization revealed *ZFY*-homologous sequences on an autosome. This was unexpected because in the marsupials, as in the eutherian mammals, male sex is determined by the Y chromosome. In light of these findings, it was concluded that *ZFY* could not be the determinant of male sex in marsupials. This meant that the mechanism of sex determination must be different in marsupials and eutherians, or if it were the same, that *ZFY* could not be the testis-determining gene in man.

The findings in mouse and marsupial seemed to argue against a testis-determining role for *ZFY*. Yet, there were other reasons for believing that *ZFY* could not be *TDF*. In their original paper, David Page and coworkers reported that the fragment defined by pDP1007 was absent in all of the XX true hermaphrodites that they studied and in some of the XX males. Male differentiation in these cases seemed to be due to constitutive mutation of autosomal or X-linked testis-determining genes downstream of *TDF*.

The argument for mutation of downstream genes in some cases of XX sex reversal was negated by the discovery of Y-DNA in XX males who lacked any trace of *ZFY*. One would not expect to find an XX male with an X-Y crossover *and* mutation in a downstream gene. So the discovery of four such males – each ZFY-negative and each carrying Y-specific sequences adjacent to the pseudoautosomal boundary – now seemed to eliminate *ZFY* as a candidate for *TDF*, and to outline a new region of the Y chromosome in which *TDF* must lie. A search of that region, comprising 35 kb adjacent to the pseudoautosomal boundary, yielded a ''new'' gene, Y-specific, and like *ZFY*, conserved across a broad spectrum of mammalian species. The new gene was called *SRY (sex-determining region Y)*.

2.4 Sex-determining Region Y Gene (*SRY*)

2.4.1 *SRY* in the Human

The *SRY* gene was discovered in 1990 by Andrew Sinclair, while he was working in the laboratory of Peter Goodfellow in London. Initially, Sinclair digested

DNA from the 35-kb region near the Y chromosome pseudoautosomal boundary, and subcloned a number of fragments, some 4 kb each. These 4-kb fragments were then cut into smaller pieces, each about 500 to 1000 bp in length (0.5–1 kb). Fifty of the fragments produced in this way were used as probes to test for corresponding fragments in DNA from males and females of the human, mouse, and bovine, and from human–hamster somatic cell hybrids containing the human X or Y chromosome. Seven of the probes identified single-copy, male-specific sequences in *Eco*R1-digested human DNA, but only one of the probes could also identify male sequences in mouse and bovine. That one was called *pY53.3*.

Because it hybridized most conspicuously with Y-DNA, a 0.9 kb *Hinc*II subclone of pY53.3 was used to assess the role of the *SRY* gene (Fig. 5). Initially, the subclone was used to probe a series of Noah's Ark blots containing DNA from male and female of several diverse species, including the human, chimpanzee, rabbit, pig, horse, bovine, and tiger. In each case, a unique male-specific sequence was identified; at reduced stringencies, additional *SRY*-like fragments were identified in male and female, indicating the presence of X-linked or autosomal *SRY*-like sequences.

In humans, the pY53.3 subclone identified a 2.1 kb male-specific fragment. When the nucleotide sequence of the human male-specific fragment was evaluated, two open reading frames were discovered. The longer of the two was found to encode 223 amino acids with a "striking similarity" to part of the Mc mating-type protein of the fission yeast, *Schizosaccharomyces pombe*, and to a conserved DNA-binding motif common among the nuclear high-mobility-group proteins, HMG1 and HMG2. Earlier, we noted that genes of fundamental significance are conserved in evolution (Sect. 2.1). The extreme evolutionary conservation of the *SRY* gene was thus consistent with its proposed critical function.

The *SRY* conserved motif – spanning 80 amino acids – was now compared with the corresponding motif of the rabbit. Sixty-four (80%) of the 80 conserved amino acids were also present in the rabbit, but only 54% similarity was revealed outside the conserved motif. In other studies, the 0.9-kb fragment of probe pY53.3 was used to test for corresponding RNA transcripts in human ovary and testis, and in male lung and kidney. A 1.1-kb transcript was

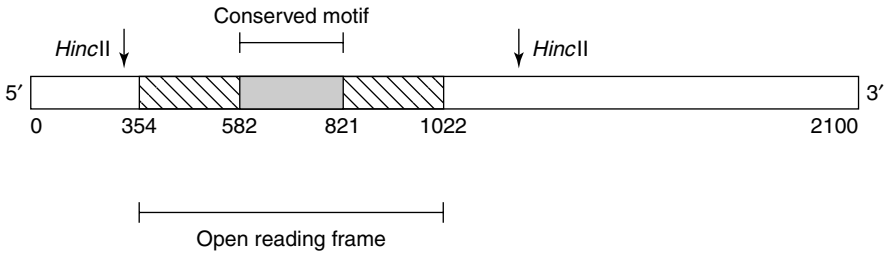

Fig. 5 Graphic representation of the 2.1 kb probe, pY53.3, which identifies *SRY*. Numbers indicate base pairs from the 5′ end; see text. [Modified after Sinclair, A.H., Berta, P., Palmer, M.S., Hawkins, J.R., Griffiths, B.L., Smith, M.J., Foster, J.W., Frischauf, A.M., Lovell-Badge, R., Goodfellow, P.N. (1990) A gene from the human sex-determining region encodes a protein with homology to a conserved DNA-binding motif, *Nature* **346**, 240–244].

identified in the testis, but not in the other male tissues, in Northern blots.

The foregoing observations – male specificity, extreme phylogenetic conservation, and testis-specific expression – seemed to confirm the proposition that *SRY* and *TDF* were the same. Yet there was room for other genes in the 35-kb pseudoautosomal fragment containing *SRY*, and it remained to be demonstrated unambiguously that *SRY* was the Y-situated gene that governed testicular differentiation. This could be done in either of the two ways: by showing that SRY was absent or mutated in sex-reversed XY women, or by showing that transgenic insertion of *SRY* could induce testicular differentiation in genetically female (XX) embryos, in the mouse for example. In fact, both conditions were met (see Sect. 6.1 and Sect. 2.4.2).

2.4.2 *SRY* in the Mouse

The mouse homolog of *SRY* was described by John Gubbay and colleagues in a paper that appeared in July 1990, in *Nature*, back to back with the paper of Sinclair et al. When the human pY53.3 was used to probe Southern blots containing DNA from male and female mice, a 3.5 kb male-specific fragment was found. This strongly hybridizing fragment was found not only in normal XY males but also in sex-reversed XX*Sxr* and XXSxr^b males.

Sxr^b, a deleted *Sxr* (Sxr^a), was the smallest fragment of the mouse Y chromosome known to contain the murine testis-determining gene corresponding to *TDF* of the human. At the time (1990), only *Zfy-1* and repetitive sequences such as *Bkm* had been identified within Sxr^b, in addition to the pY53.3-hybridizing sequence. Thus, pY53.3 had now defined a novel single-copy sequence corresponding to *SRY*, in the smallest region of the mouse Y chromosome known to be male-determining.

Further analysis revealed a mouse clone, p4.2.2 containing a 380 bp mouse fragment that hybridized at high stringency only to the Y-specific 3.5 kb band. This indicated that clone p4.2.2 contained the mouse homolog of pY53.3. When the clone was sequenced in the region of homology with pY53.3, a 62% similarity was observed, and a long open reading frame corresponding to one of the reading frames in *SRY* (and to another open reading frame in the rabbit homolog of *SRY*). These observations signaled the presence of a new gene, which was called *Sry*.

When *Sry* was evaluated further, a 237-bp fragment was found within the open reading frame, which had an 80% sequence similarity to the corresponding fragment within pY53.3. As with its human homolog, the mouse *Sry* gene exhibited a remarkable similarity to the conserved 80-amino acid motif of the fission yeast *S. pombe*, an extraordinary finding given the phylogenetic distance between yeast and mammals. And like its human counterpart, *Sry* was shown to encode a protein with a DNA-binding motif. Moreover, *Sry* RNA transcripts were detected in the urogenital ridge of 10.5-day-old male embryos – just before differentiation of the testis – but not in the corresponding tissue of 10.5-day-old female embryos.

Compelling evidence for a sex-determining role of *Sry* came a year later, when the gene was found to induce testicular differentiation if introduced as a "transgene" into XX embryos of the mouse. A 14-kb fragment containing *Sry* was injected into fertilized eggs and the eggs were transferred into the oviducts of pseudopregnant females. The resulting embryos were recovered at 14 days and the

gonads scored histologically. Most of the 158 embryos obtained in that way were normal XY males or XX females, but 8 of the XX embryos were transgenic, and of those, 2 had testes. Both lacked *Zfy-1*; both carried "many copies of *Sry*".

In other experiments, injected embryos were allowed to develop to term. Among the 49 males and 44 females that were born, Southern blotting revealed 5 that were transgenic. Two were XY males and two were XX females (later found to be fertile). The last was a sex-reversed XX male. In May 1991, that mouse was pictured on the cover of *Nature*.

Thus, the search for the Y-situated testis-determining gene had come to an end. In summary, about 25% of the transgenic mice – those in which *Sry* had been incorporated – developed as males. This was due to *Sry*, because sequencing revealed no genes other than *Sry* in the injected 14-kb fragment. Human *SRY* did not function as a sex determinant when it was injected into the mouse embryos. But this was not surprising given the degree of sequence divergence (23 of 79 amino acids) within the DNA-binding motif of the human and mouse homologs. Yet, *SRY* was shown to be the human testis-determining gene, because mutation within the *SRY* conserved motif was found in cases of human XY sex reversal (see discussion in Sect. 6).

2.4.3 *SRY* in Other Species

Location of *SRY* in marsupials is of interest because, as noted earlier, the *ZFY* gene is autosomal in marsupials. The marsupial mammals (Metatheria) diverged from placental mammals (Eutheria) some 100 to 150 million years ago. Since the Y chromosome is sex-determining in both groups, it would seem likely that the testis-determining gene of each is derived from a common ancestral gene. Conservation of a common Y-specific sequence might thus be expected.

On this basis, a group of Australian and British geneticists set out to identify the marsupial homolog of SRY by using the 0.9 kb subclone of the human pY53.3 probe. Southern blots were prepared from the DNA of two marsupial species representing major orders that diverged some 50 million years ago: *Macropus eugenii*, the tammar wallaby, and *Sminthopsis macroura*, the stripe-faced dunnart, a small mouse-like carnivore. Male-specific fragments were detected in each of the two species, and in addition, a number of fragments shared by male and female.

Next, the pY53.3 probe was used to screen a cDNA library constructed from testis RNA of *S. macroura*. A positive clone was obtained and used to probe Southern blots for *SRY* homologs. It hybridized at high stringency to DNA from males but not from females, indicating that it had been derived from a Y-specific transcript.

Further study pointed to the existence of a Y-specific marsupial gene having a region of homology with the human *SRY* gene, and an open reading frame encoding an HMG type box of 79 amino acids (82 and 86% similarity with human *SRY* within the conserved domains of *S. macroura* and *M. eugenii*, respectively). Thus, unlike *ZFY*, the marsupial *SRY* gene appeared to be on the Y chromosome; this was later confirmed by *in situ* hybridization. These findings provided evidence for a monophyletic origin of the mammalian Y chromosome, and supported the notion that the sex-determining gene is the same, or at least similar, in eutherian and marsupial mammals.

SRY is not limited to the mammals. Using a probe from the conserved motif

of the human *SRY* gene, geneticists at the University of Tennessee in Memphis screened genomic DNA from 23 different species representing 5 vertebrate classes, 400 million years of vertebrate evolution, and several alternative modes of sex determination. Among the species studied were the chicken, in which the female is the heterogametic sex (ZW), the alligator, in which sex is determined by temperature, and the sex-changing wreckfish, *Anthias squamipinnis*, in which all fish begin life as females (Table 1). In Southern blots, positive hybridization was observed in every case – in males and females. Although there was no sex-specific reaction outside of the mammals, and the function of *SRY*-like sequences in the nonmammals remained to be determined, these findings underscored the importance of the *SRY* sequence.

2.4.4 The SRY Protein

In the adult human testis, the predominant *SRY* transcript derives from a single exon. The transcript includes the open reading frame for a protein of 204 amino acids. Initial evaluation of the *SRY* nucleotide sequence revealed that it could encode a protein with DNA-binding properties. As noted in Sect. 2.4.2, the 80-amino acid conserved motif within the SRY protein is common among certain proteins known to have DNA-binding activity – namely, the high-mobility-group proteins. These proteins bind to DNA in a nonspecific manner, although variants can function as sequence-specific transcription factors.

The ability of the SRY/Sry protein to bind DNA has been demonstrated in several studies. For example, IRE-ABP is a rat protein that complexes to the IRE-A insulin response element

Tab. 1 Phylogenetic conservation of *ZFY* and *SRY*.

Class	*Species*	*Mechanism of sex determination*	*ZFY hybridization in*	*SRY hybridization in*
Mammalia	Human	XX/XY	Male (female)[c]	Male
	Mouse	XX/XY	Male (female)[c]	Male
	Kangaroo	XX/XY	Male, female	Male

Source: After Wachtel, S.S., Tiersch, T.R. (1994) The Search for the Male-determining Gene, in: Wachtel, S.S. (Ed.) *Molecular Genetics of Sex Determination*, Academic Press, San Diego, CA, pp. 1–22.

of the glyceraldehyde-3-phosphate dehydrogenase gene. The IRE-ABP protein contains a single HMG box with 67% similarity to the corresponding HMG box in mouse *Sry* and 98% similarity to the HMG box in mouse Sry-like protein, a4. Fusion proteins incorporating the HMG of Sry or IRE-ABP, or both, bind to the IRE-A target site, 5′-TTCAAAC-3′; binding is inhibited by mutations within the Sry fusion protein.

The human SRY protein resembles two T-cell proteins: TCF-1 and TCF-1α. The former binds to the sequence 5′-AACAAAG-3′, which occurs in several T-cell genes, including the CD3ε enhancer (the AACAAAG sequence also occurs upstream of the *SRY* and *Sry* genes). Geneticists in England therefore induced production of SRY protein in *Escherichia coli* and Sf9 insect cells, and tested the protein for ability to bind the TCF-1 target sequence, AACAAAG, and variants of the sequence. SRY protein was incubated with double-stranded oligonucleotides, and the resulting complexes were studied in an electrophoresis mobility shift assay. Wild-type SRY formed complexes with oligonucleotides containing AACAAAG, but binding was negligible when that sequence was replaced with CCGCGGT or when mutant SRY from XY women was substituted. Binding did not occur when single-stranded DNA was used.

Subsequently, it was found that SRY protein, like HMG1, recognizes four-way junctions regardless of their sequence. Four-way junctions, rare structures induced in DNA by recombination or by intrastrand base pairing of inverted repeat sequences, resemble the four arms of an X in a plane, with two angles of about 120° and two angles of about 60°. Moreover, a sharp bend is produced in linear DNA when SRY binds to the AACAAAG sequence. Thus, the interaction between HMG boxes and DNA seems to involve specific structures.

In December 1994, a group headed by Patricia Donahoe and Michael Weiss reported that SRY protein could activate transcription of the *AMH* gene. Transcription was found to be secondary to partial side-chain insertion of the *SRY* conserved motif in a widened minor groove. This implied that expression of *AMH* was dependent on a normal function of *SRY*, or in other words, that *AMH* was a downstream component of the *SRY* pathway.

Given the phylogenetic conservation of *SRY* and the apparently identical function of *SRY* and *Sry* genes in man and mouse, it is remarkable that human and mouse SRY proteins exhibit disparate binding properties. Whereas the HMG domains of human and mouse SRY (hSRY and mSRY) both recognize the sequence 5′-AACAAAG-3′, mSRY recognizes another sequence, 5′-AACAATG-3′, with significantly greater affinity. Moreover, in situations in which hSRY and mSRY react with the same nucleotide sequences, the mouse and human HMG domains may exhibit different flexing (bending) properties. And on binding to DNA, mSRY develops prominent major groove contacts compared to hSRY. These findings and sequence differences outside the HMG box could explain why human SRY does not induce testicular differentiation in transgenic XX mice.

3
X-linked Sex-determining Genes

3.1
Scandinavian Wood Lemming

The wood lemming, *Myopis schisticolor*, is a small mouse-like rodent that inhabits the

mossy grasslands of Scandinavia. Unlike its cousin, *Lemmus lemmus*, notorious for its frenetic migrations, this quiet species is remarkable for a 4 : 1 sex ratio, favoring the female. There are two kinds of female: one has two X chromosomes, and the other has an X and a Y. The XY females are fertile and anatomically indistinguishable from their XX sisters.

Cytogenetic analysis reveals a normal Y chromosome in the XY females. In fact, it is a modified X that causes sex reversal. There are two kinds of X chromosome in the wood lemming, identifiable by differential Giemsa-banding in the short arm (Xp). One, denoted X, is found in XY males; the other, denoted X*, is found in X*Y females. Since XO rodents become fertile females, it is not surprising that X*Y females of the wood lemmings are fertile.

These observations point to the occurrence in wood lemmings of an X-linked gene, perturbation of which can block the function of the Y chromosome. But according to Ohno's Law, a gene that is on the X chromosome in one mammalian species will be on the X chromosome in other mammalian species. This implies occurrence of an X-linked sex-reversing gene in species such as the human.

3.2
Genealogical Evidence in the Human

In Sect. 6.1.1, we describe the syndrome of *XY gonadal dysgenesis*, which results from a failure of the testis-determining pathway in XY fetuses. Affected fetuses develop ovaries initially, but in humans, two normal X chromosomes are needed to sustain ovarian differentiation. In 45,X and 46,XY human embryos – those lacking a second X chromosome – the ovaries degenerate and are represented at around the time of birth by "streak gonads," which are functionally inert. Women with XY gonadal dysgenesis are accordingly sterile and, in general, eunuchoid.

As might be expected, some of these cases are due to mutation within the *SRY* gene, but familial clusters are known in which the condition is transmitted as an X-linked trait (Fig. 6). This seems to vindicate the requirement of Ohno's Law, yet there is even more compelling evidence for an X-linked sex-reversing gene.

3.3
Mapping Studies: The *DAX1* Gene

In 1980, an anomalous additional band was found in the short arm of the X chromosome in a profoundly retarded girl with cleft palate, skeletal malformations, and various other congenital anomalies. The girl had an XY chromosome pair. The karyotype was designated 46,dup(X)(p21→pter),Y, signifying a duplication extending from Xp21 to the Xp terminus. When the girl died at 5 years of age, postmortem studies revealed small uterus and fallopian tubes, and ovarian-like stroma containing a few degenerative follicles. There was no sign of testicular tissue. And the external genitalia were those of a normal female.

The abnormal X chromosome was inherited from the mother (Fig. 7). When the mother became pregnant again, amniocentesis revealed a fetal XY karyotype with the abnormal X chromosome. The pregnancy was terminated at 20 weeks. The fetus was a female with multiple congenital defects similar to those of the propositus. External and internal genitalia resembled those of a normal female fetus of that age; the gonads were fetal ovaries.

Other cases of XY sex reversal involving Xp duplication have been reported. In 1994, a group of American geneticists

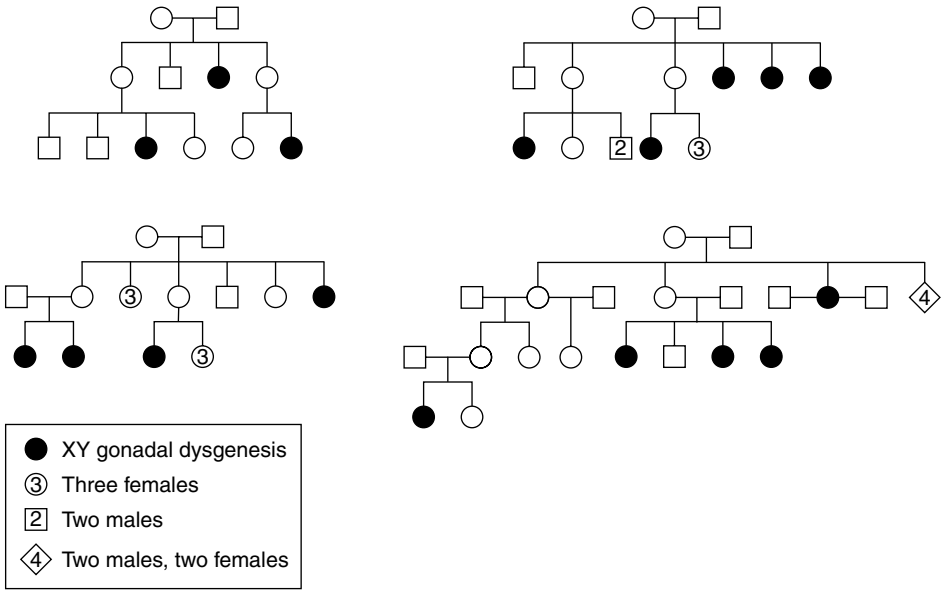

Fig. 6 Familial aggregates of XY gonadal dysgenesis consistent with transmission of an X-linked gene. (From Wachtel, S.S., Tiersch, T.R. (1994) The Search for the Male-determining Gene, in: Wachtel, S.S. (Ed.) *Molecular Genetics of Sex Determination*, Academic Press, San Diego, CA, pp. 1–22).

headed by Pamela Arn described maternal half siblings with ambiguous external genitalia and a small duplication in Xp: in both children, the karyotype was 46,X,dup(X)(p21.2→p22.11),Y, signifying duplication of the region Xp21.2→p22.11. Except for undifferentiated gonads and external genitalia, these children manifested none of the abnormalities found in other sex-reversed patients with duplications in the Xp21 region. This could be explained by the limited size of the duplication in these cases.

In light of these findings, a ''new'' sex-reversing gene, *SRVX (sex reversal X)* was assigned to the region Xp21.2→p22.11, comprising a few megabases distal to the ornithine transcarbamalase (*OTC*) locus. It was inferred (i) that perturbation of this gene, as in cases of Xp21 duplication, could block male differentiation of the gonad, despite presence of an intact *SRY* sequence; (ii) that some cases of XY gonadal dysgenesis could be due to *submicroscopic* duplication involving the *SRVX* locus; and (iii) that the new gene was part of a pathway of testis-determining genes that includes *SRY*.

By evaluation of overlapping duplications, Italian geneticists narrowed the locus of the new gene to a 160-kb region of Xp21 adjacent to the adrenal hypoplasia congenita locus and within roughly 100 kb of *DXS319*. They called the gene *DSS* for *dosage sensitive sex reversal*, and confirmed that having two active copies of the gene blocks male development in XY embryos. Since the gene was found to be absent in certain males, it could not be required for differentiation of testes, and thus could not be a regular part of the male-determining pathway.

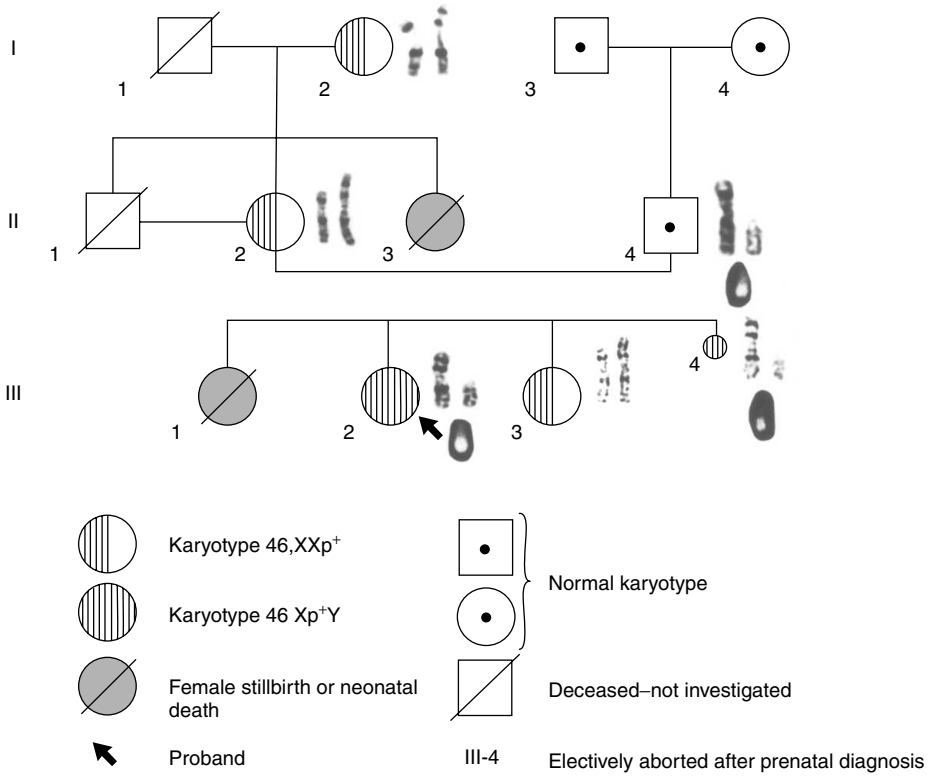

Fig. 7 XY sex reversal caused by inheritance of duplicated X chromosome. The duplicated band was found in the short arm of the X chromosome in the maternal grandmother (I-2), mother (II-2), and normal sister (III-3) of the proband, and in the proband (III-2, arrow) and her sex-reversed fetal sibling (III-4). The father's chromosomes (II-4) were normal. Giemsa-banded chromosomes with quinacrine-stained inserts. [From Bernstein, R., Koo, G.C., Wachtel, S.S. (1980) Abnormality of the X chromosome in human 46,XY female siblings with dysgenetic ovaries, *Science* **207**, 768–769].

Today, the relevant gene is called *DAX1* for *dosage sensitive sex reversal-adrenal hypoplasia congenita-critical region of the X chromosome, gene 1*. The *DAX1* gene is one of the nuclear hormone receptor superfamily. It encodes a nuclear protein that binds DNA and regulates transcription mediated by the retinoic acid receptor. Mutations in *DAX1* cause adrenal hypoplasia congenita but do not affect sex determination in human males. In mice, XX embryos lacking both copies of the *Dax1* gene become females (evidently *DAX1* is not an essential component of the sex-determining pathway in males or females).

In mouse embryos, *Dax1* is expressed in the somatic cells of the indifferent gonad regardless of karyotype, but it is downregulated in the developing testis. These observations suggest that, in addition to its endocrinological function, *DAX1* acts as an antagonist to *SRY*. Thus, duplication of *DAX1* blocks *SRY*-mediated differentiation of the embryonic testis.

4
Autosomal Sex-determining Genes

4.1
Genealogical Evidence in the Human

The syndrome of XY gonadal dysgenesis can occur in familial clusters, and can be caused by transmission of an X-linked gene. In some families, however, the frequency of affected relatives is consistent with the frequency that would be expected if the condition were inherited as a male-limited autosomal trait. It seems reasonable to assume that autosomal genes are involved in the etiology of at least some women with XY gonadal dysgenesis, because most cases are sporadic, and *SRY* mutations are found in a minority of XY women (20% or less). Moreover, if *SRY* encodes a transcription factor, it should activate other genes in the testis-determining pathway (Table 2). And *SRY/Sry* itself may be activated by other genes (see Sect. 7).

Tab. 2 Genes of the human male sex-determining cascade.

Gene	*Locus*	*Presumptive function(s)*
SRY	Yp11.3	Initiator of the testis-determining pathway
SOX9	17q24.1-q25.1	Sertoli cell differentiation,[a] positive regulation of AMH
WT1	11p13	Tumor suppressor; formation of indifferent gonad, testis (?)
SF1	9p33	Formation of indifferent gonad, testis (?) regulation of AMH
DAX1	Xp21.2	Antagonist of *SRY*
WNT-4	1p35	Formation of indifferent gonad

[a] Evidently, *SOX9* is an immediate downstream target of *SRY*.

4.2
Mapping Studies: The *SOX9* Gene

Campomelic dysplasia is a human syndrome characterized by bowing of the long bones, dwarfism, cleft palate, and various other congenital malformations. Owing to the severity of the condition, affected children usually die within a few weeks or months of birth. Patients with campomelic dysplasia can be XX or XY, but some two-thirds of those with XY are sex reversed. A typical case might involve a stillborn XY female with undifferentiated gonads, slightly enlarged clitoris, and normal uterus and fallopian tubes.

Study of *de novo* reciprocal translocations of chromosome 17 in three different patients with this condition allowed geneticists to assign the genes for campomelic dysplasia and associated sex reversal to the chromosome region 17q24.3→q25.1. Fluorescence *in situ* hybridization with chromosome painting probes showed that the translocated segment comprised about 15% of chromosome 17 in each of the subjects. This was consistent with occurrence of breakpoints at the interphase between 17q24-q25, distal to the GH locus (growth hormone) and proximal to *TK1* (thymidine kinase). Two of the patients were XY females; one was an XX female. The karyotypes were

46, XY,t(7; 17)(q32; q24.2) or

46, XY,t(7; 17)(q34; q25.1)

46, XY,t(13; 17)(q22; q25.1)

46, XX,t(1; 17)(q42.13; q24.3 or q25.1).

The foregoing observations signaled the presence of a sex-determining gene (initially called *SRA1*) on chromosome 17 (association of campomelic dysplasia and sex reversal could be due to a single mutation affecting two developmental pathways, or to a deletion involving contiguous genes). Today the gene is called *SOX9*.

We have indicated that *SRY* belongs to a group of genes that code for HMG proteins. In aggregate, these constitute the *SOX (SRY-like HMG box)* family of genes. It is remarkable that duplication of *SOX9* can cause XX sex reversal – that is, it can induce the formation of XX testes – in the absence of *SRY*, and that SOX9 is the first marker to appear in newly differentiated Sertoli cells. These observations suggest that *SOX9* is an early downstream target of *SRY* (Fig. 1). In fact, mouse *Sox9* is expressed on day 10.5 in the indifferent embryonic gonads of male and female. But when *Sry* is expressed on day 11.5 – the time of differentiation of the mouse testis – transcription of *Sox9* is increased in the male and decreased in the female.

4.3 Other Autosomal Sex-determining Genes

There is evidence for autosomal sex-determining genes other than *SOX9*. Thus, for example, cases of XY sex reversal have been reported in patients with deletions in chromosome 9p. In one case, the subject was an XY female with a *de novo* 9p deletion and streak gonads but no other dysmorphic features. The *SRY* gene was intact.

4.3.1 The *SF1* Gene

In fact, the *SF1 (steroidogenic factor)* gene on chromosome 9 has a significant role in the embryogenesis of the adrenal gland and gonad in humans, and in mammals generally. In humans, mutation of the *SF1* gene leads to adrenal failure and XY gonadal dysgenesis. In mice with homozygous deletions of *SF1*, the gonads and adrenals both fail to develop, and the affected young die shortly after birth. Since these organs initiate development but do not finish it, *SF1* may participate in the development of the indifferent gonad, but not directly in testicular organogenesis. The *SF1* gene is on human chromosome 9p33, and contains a conservative DNA-binding motif consisting of two zinc fingers.

4.3.2 The *WT1* Gene

Wilms tumor of the kidney accounts for 15% of cancers in children. It may be found together with aniridia, urogenital malformations, and mental retardation (WAGR syndrome). The tumor develops after mutation or loss of the *WT1* tumor suppressor gene on chromosome 11p13. Affected XY children have gonadal dysgenesis, suggesting a role for the *WT1* gene in development of the testis. The gene contains 10 exons, which generate 24 isoforms, some of which can activate *SRY* and *DAX1* promoters *in vitro*.

4.3.3 The *WNT-4* Gene

The *WNT-4* gene is on human chromosome 1p35. The WNT-4 protein is a member of a family of locally acting cellular growth factors. The gene is expressed in the mesonephros and in the adrenal gland in both sexes. In females, WNT-4 signaling is required for development of the Müllerian ducts and for differentiation of oocytes and interstitial cells. *WNT-4* is downregulated in the developing testis. In mice, deletion of *Wnt-4* causes XX sex reversal. And in humans, duplication

of the WNT-4 region on chromosome 1 causes XY sex reversal. Moreover, *Wnt-4* upregulates *Dax1*, so duplication of *Wnt-4* would be expected to suppress expression of *Sry*. These observations suggest a key role for *Wnt-4* signaling in gonadal sex determination.

5
XX Sex Reversal

5.1
XX Males

5.1.1 In the Human

Males with female sex chromosomes (46,XX) were first described in 1964. A chief feature of the XX male syndrome is the small, sterile testis, although in general, XX males are normal-appearing. The testicular cords are narrower than those in normal men and consist of Sertoli cells only (Fig. 8). Female-like breasts develop in about one-third of XX males, and hypospadias is present in some cases. The syndrome occurs with a frequency of about 1/20 000 male births.

Testicular development in the absence of a Y chromosome could be explained by constitutive activation of downstream testis-determining genes, or alternatively, by Y-X translocation. These conditions – constitutive mutation and Y-X translocation – would be represented by two classes of XX male, one lacking the *SRY* gene (Y−) and one having it (Y+). So it is remarkable that two such classes have now been identified, and that the Y(−) XX males are notable for female-like breasts (gynecomastia), cryptorchid testes, and abnormal external genitalia – traits uncharacteristic of Y(+) XX males.

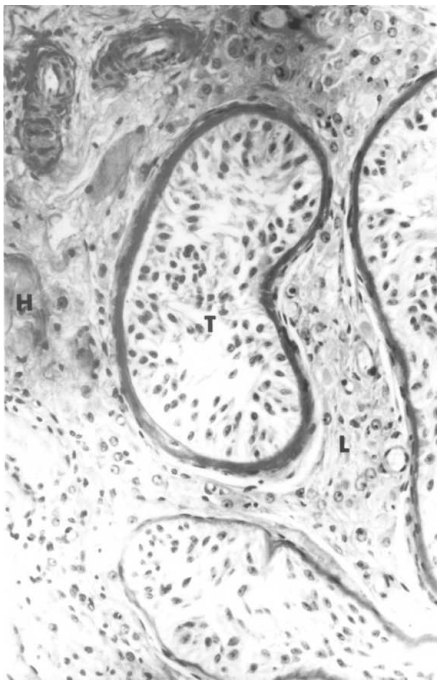

Fig. 8 The XX testis. Section of testicular biopsy from a 20-year-old 46,XX male. Some of the tubules are hyalinized (H). Some (T) are notable for thickening of the basement membrane, and are lined with Sertoli cells only; germ cells are absent. Leydig cells (L) are present in the interstitium. This photomicrograph was the generous gift of Professor Albert de la Chapelle. (From Wachtel, S.S., Bard, J. (1981) The XX Testis, in: Laron, Z. (Ed.) *The Intersex Child*, Karger, Basel, pp. 116–132).

In summary, then, most XX males are *SRY*-positive, due to X;Y translocation, but some are *SRY*-negative. Absence of *SRY* in XX males – implying mutation of downstream genes, or duplication, as in the case with *SOX9* – is associated with gynecomastia and abnormality of the external genitalia. Occasionally, XX males occur in kindreds with other XX males (and sometimes in kindreds with XX true hermaphrodites). These XX males usually lack Y-DNA (Sect. 5.2).

5.1.2 In the Mouse

XX males of the mouse were first described in 1971. Sex reversal in these animals was attributed originally to mutation of an autosomal gene, *Sxr*. But as noted in Sect. 2.2, the XX*Sxr* males were found to be the product of a recurrent nonreciprocal Y-X crossover involving the sex-determining region of the Y – namely, the *Sxr* region. Since XX*Sxr* males are sterile, the condition is transmitted by carrier XY*Sxr* males. The carriers produce four kinds of sperm – X, X*Sxr*, Y, Y*Sxr* – and thus four kinds of offspring: fertile XX females, XX*Sxr* sex-reversed males, XY males, and carrier XY*Sxr* males (Table 3). In 1984, certain XX*Sxr* males were found to lack the male-specific H-Y antigen (thereby excluding *Hya* as a candidate for *TDF*). This was due to a deletion within the *Sxr* region. The deletion was called Sxr^b to distinguish it from the nondeleted *Sxr*, called Sxr^a (Sect. 2.4.2).

Analysis of the *Sxr* region has revealed the presence of several genes: *Sry*, the testis-determining gene; *Hya*, the gene controlling expression of the H-Y antigen; *Spy*, a gene involved in spermatogenesis; *Zfy-1* and *Zfy-2*, homologs of human *ZFY*; and *Ube1-y1* and *Ube1-y2*, genes involved in ubiquitin-mediated protein metabolism. Of these, *Hya*, *Spy*, and *Zfy-2* are not found in the Sxr^b deletion, which comprises at most, 320 kb of DNA. The breakpoints of the deletion fall within the *Zfy* genes; Sxr^b thus includes a fusion gene whereby the 5′ promoter of *Zfy-2* is joined to the coding region of *Zfy-1*.

Tab. 3 Four kinds of offspring produced by XY*Sxr* carrier males.

Sperm	*Progeny*	*Sex phenotype*	*Bkm foci*[a]
X	XX	Fertile female	None
Y	XY	Noncarrier male	Y
X*Sxr*	XX*Sxr*	Sex-reversed male[b]	X
Y*Sxr*	XY*Sxr*	Carrier male	Y

[a] Rich clusters of *Bkm* normally associated with the sex-determining region of the mouse Y chromosome.
[b] XX males are sterile.

5.1.3 In the Goat

Hornlessness in goats is caused by a dominant autosomal gene initially called *P (Polled)*. Goats heterozygous for the polled gene ($P/+$) are therefore born without horns, but they are otherwise unaffected. Goats homozygous for polled (P/P) are also born without horns but XX$P/P$ goats have testes or ovotestes and exhibit a range of sexual phenotypes varying from nearly normal male to hermaphroditic female. So *P* acts as an autosomal recessive testis-determinant.

In December 2001, geneticists in France reported that polled sex reversal is due to deletion from chromosome 1q43 of an 11.7-kb DNA fragment consisting mostly of repetitive sequences. Evidently, the deletion impedes transcription of two linked genes, one of which, *PISRT1*, may affect transcription of *SOX9*. According to one scheme, *PISRT1* normally inhibits the testis-inducing function of *SOX9*, and when *PISRT1* is deleted, as in XX*P*/*P* goats, *SOX9* induces the testicular cascade, even in the absence of *SRY*.

5.1.4 In the Dog

XX sex reversal is not uncommon among certain breeds of the dog, notably the cocker spaniel and Weimaraner. In 1978, veterinarians at the University of Pennsylvania described an XX male pup with undescended right testis, small penis with hypospadias, and hypoplastic uterus. Taken together, these findings were not surprising, as XX males had already been described in the cocker spaniel. But the subsequent finding was extraordinary.

The mother of the XX male was grossly female in appearance, but surgical exploration revealed that she had bilateral ovotestes, each containing prominent ovarian follicles and well-developed testicular tubules. She was a true hermaphrodite. The XX male pup had inherited his testicles from his mother.

These observations support the view that XX male syndrome and XX true hermaphroditism are alternative faces of the same coin. Other XX males and XX true hermaphrodites have been discovered in the extended pedigree, findings consistent with transmission of an autosomal or X-linked gene.

5.2 XX True Hermaphrodites

5.2.1 In the Human

There are numerous references to hermaphrodites in the ancient literature, for example, in Plato's *Symposium* and Ovid's *Metamorphoses*. The earliest reference appears in the cuneiform tablets unearthed at the site of the Royal Library at Nineveh (7th century BCE), and an account of the religious and social obligations of hermaphrodites appears in the *Mishnah*, *Bikkurim 4:1–5*, representing an oral tradition committed to writing nearly 2000 years ago.

According to our modern designation, a true hermaphrodite is a person with ovarian and testicular tissue – in particular, ovarian follicles and testicular tubules – in separate gonads or in a single gonad called the ovotestis. Simultaneous occurrence of male and female gonadal tissue is often associated with pronounced ambiguity of the secondary sex traits. The condition may be found in patients with a variety of karyotypes such as 46,XX or 46,XY, and mosaic complements such as 46,XX/46,XY. But 60% of human true hermaphrodites are 46,XX, raising the question, as in the case of XX males, how testicular differentiation can occur in the absence of the Y chromosome (i.e. in the absence of *SRY*).

Whereas X;Y translocation is common among XX males, it is uncommon among XX true hermaphrodites. When 35 XX true hermaphrodites were screened for Y-DNA sequences including *SRY*, the *SRY* sequence was found in only 4. This indicated that gene mutation is a likely cause of XX true hermaphroditism. And that was borne out in genealogical studies. Earlier (Sect. 5.1.1), we noted that XX males and XX true hermaphrodites sometimes occur in the same kindred. In

one such instance, the proband was an XX true hermaphrodite with prominent gynecomastia, small penis, hypospadias, and scrotal ovotestes. A brother of the proband was unaffected, but he sired an XX true hermaphrodite with ambiguous genitalia and bilateral ovaries with an appended right testis. Another unaffected brother sired two XX males: one had a small phallus with severe chordee, hypospadias, and hypoplastic testes, but no ovarian tissue; the other had similar traits. An autosomal sex-reversing gene was indicated in the pedigree (Fig. 9). In another similar family, an XX male and his XX true hermaphrodite sibling had a cousin who was an XX true hermaphrodite. *SRY* was not present in any of the affected family members.

Absence of Y-DNA in XX true hermaphrodites and some XX males points to genes other than *SRY* in the development of the normal testis. Although cryptic Y-bearing cell lines in the gonad cannot be ruled out in sporadic cases of XX sex reversal, occurrence of XX males and XX true hermaphrodites in families is consistent with transmission of autosomal sex-reversing genes (discussed in Sect. 4).

6
XY Sex Reversal

6.1
XY Females

6.1.1 In the Human

As noted in Sect. 3.2, two X chromosomes are required for differentiation of the normal human ovary. In 45,X human embryos, the ovary develops normally during the first trimester, but the germ cells die and the follicles become atretic. The gonads are represented later by fibrous streaks of connective tissue devoid of endocrinologic activity. The resulting condition is called *Turner syndrome*.

According to Susumu Ohno, the X and Y chromosomes evolved from a pair of homologous autosomes; the Y lost most of its genetic material to become a specialized testis inducer while the X remained invariant. Accordingly, when the sex-determining function of the Y chromosome is lost or compromised, the XY gonad develops in the same way as the XO gonad. The resulting condition, called *XY gonadal dysgenesis*, or *Swyer syndrome*, is characterized by primary amenorrhea and delayed puberty, and occurs in about one of

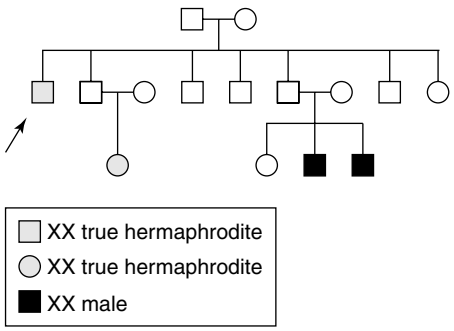

Fig. 9 Family with XX true hermaphrodites and two XX males. The propositus (arrow) was a masculinized true hermaphrodite with scrotal ovotestes. The genealogy is consistent with transmission of an autosomal sex-reversing gene. [On the basis of the study by Skordis, N., Stetka, D.G., MacGillivray, M.H., Greenfield, S.P. (1987) Familial 46,XX males coexisting with familial 46,XX true hermaphrodites, *J. Pediatr.* **110**, 244–248 (1987). From Wachtel, S.S. (1994) XX Sex Reversal in the Human, in: Wachtel, S.S. (Ed.) *Molecular Genetics of Sex Determination*, Academic Press, San Diego, CA, pp. 267–285].

20 000 female births. In addition to having nonfunctional streak gonads, women with XY gonadal dysgenesis have a significant risk of developing germ cell tumors such as gonadoblastoma and dysgerminoma (25–35%).

When the *SRY* gene was cloned, geneticists tested its function by evaluating the *SRY* sequence in women with XY gonadal dysgenesis. Mutation or loss of the *SRY* gene would explain failure of male development in these women, and would help to confirm its testis-determining role. Testing was accomplished by amplifying the *SRY* conserved domain in the polymerase chain reaction (PCR), then evaluating the nucleotide sequence of the PCR product, and comparing it to the sequence in normal XY males. By the end of 1993, more than a hundred cases of XY gonadal dysgenesis had been studied in this way. *De novo* mutations within the *SRY* conserved domain (the HMG box) were identified in about 15% of those cases.

Other mutations were detected in at least five of the affected women: they had male relatives with the same mutation. In one kindred, a T→C transition caused a phenylalanine-to-serine change at amino acid position 109 in the propositus and in the father, two brothers, and an uncle. No decrease in DNA-binding activity was observed when the mutant SRY protein was compared with wild-type SRY against the 5′-AACAAAG-3′ target site (see Sect. 2.4.4). In another family, a G→C substitution causing a valine-to-leucine change was identified at position 588 of pY53.3 in two XY female siblings, and in the father, a paternal uncle, and a paternal aunt (also an XY female). These familial variants might have been no more than benign polymorphisms (which would explain their presence in normal males). Alternatively, the same mutation might have had different effects in different individuals, depending on the genetic background.

Mutation in the *SRY* conservative domain in cases of XY gonadal dysgenesis was consistent with the putative sex-determining role of the *SRY* gene, but the low frequency of *de novo* mutations suggested other causes of the syndrome, and in particular, other genes in the sex-determining pathway. Mutation outside the HMG box could also account for a proportion of cases. A precedent was described in 1992, in a case involving a deletion 1.7 kb upstream of the *SRY* transcription initiation site. The deletion comprised some 25 to 50 kb of DNA, 5′ to *SRY* in the Y chromosome short arm.

Other forms of XY gonadal dysgenesis, namely those caused by perturbation of X-linked or autosomal genes, are discussed in Sects. 3 and 4.

6.1.2 In the Mouse

XY sex reversal XY females of the laboratory mouse, *Mus musculus*, were originally sired by a chimeric male produced with embryonic stem cells infected with a retrovirus. Because sex reversal was inherited with the Y chromosome, the mutation was designated $Y^{Tdy.m1}$, or Y for short. Later, when the mouse *Srγ* gene was isolated, geneticists learned that it was deleted in XY females. Mapping studies showed that the deletion comprised nearly 11 kb of DNA, but did not include the *Zfy1* and *Zfy2* genes. Proviral sequences were not detected. The XY females were fertile but their reproductive lifespans were foreshortened, and they produced small litters.

XYd sex reversal When certain males of the mouse subspecies, *M. m. domesticus*,

are crossed with females of the inbred strain C57BL/6 (B6), the F_1 males are normal. But in subsequent backcrosses (B6 females × *N*) (where *N* = the backcross generation number), XY females and XY hermaphrodites are produced. This became known as XYd sex reversal (d = *domesticus*). On cytogenetic analysis, the Y chromosomes of the sex-reversed mice were indistinguishable from those of normal XY males. In Southern blots, hybridization patterns were also indistinguishable when DNA samples from XY males and XYd females were tested with Y-specific probes including *Sry*.

Because these findings indicated that XYd sex reversal was not due to a mutation of the Y chromosome, geneticists proposed that the testis-determining gene of the *M. m. domesticus* subspecies (Sry^{Dom}) could not interact functionally with an autosomal gene in the B6 strain, which they called *tda-1* (testis-determining autosomal-1). Hence, Sry^{Dom}, *tda-a*/*tda-1* mice could become females or hermaphrodites, but not males. The absence of sex-reversed XY females in the F_1 generation could be explained by the presence of the *M. domesticus* dominant *Tda1* allele in all of the XY (heterozygous) offspring. In subsequent backcross generations, however, the probability of inheriting the dominant *Tda1* allele would be reduced. In the first backcross generation, 25% of all autosomal loci would be homozygous for B6 alleles. In the sixth backcross generation (N6), nearly 100% of the autosomal genes would be of B6 origin, and in fact, all XY progeny in N6 have become females or hermaphrodites.

Several inbred mouse strains were found to have Y chromosomes of *M. m. domesticus* origin (e.g. Posch-1, AKR and SJL) although sex reversal was unreported in these strains. When the Posch-1 Y chromosome was introduced by backcrossing into the B6 genetic background, the results were the same as those just described. When the AKR Y chromosome was introduced, ovotestes were observed in 14- to 16-day-old embryos, but the ovotestes became virilized, and there was no evidence of sex reversal after birth. When the SJL Y chromosome was introduced, normal testes developed; ovotestes were found in only 1 of 87 fetuses. Thus, not all Y^{Dom} chromosomes could generate XYd sex reversal in the B6 strain.

Later, in Southern blots of DNA from AKR and SJL, alternative hybridization patterns were identified with Y-specific probes. Genetic heterogeneity was confirmed when sequencing revealed that *Sry* is polymorphic in the different *M. m. domesticus* Y chromosomes. Thus, although the precise mechanism of XYd sex reversal remained to be determined, *Sry* polymorphism could contribute to the different testis-inducing capacities of the Y^{Dom} chromosome in B6 mice.

T-associated sex reversal The *H-2*-linked T-locus mutants of the mouse block normal development of the notochord and generate phenotypes that can vary from loss of the entire notochord to occurrence of minor abnormalities of the tail. When the T^{hp} (T hairpin tail) mutation was being introduced into the B6 genetic background, geneticists noted that at the N3 and N4 backcross generations, XY fetuses with T^{hp} were females or hermaphrodites. This required backcrossing to the B6 inbred strain, and presence of an AKR Y^{Dom} chromosome; sex reversal did not occur when the T^{hp} mutation was backcrossed into the C3H strain, or when a non-AKR Y was present.

Since T^{hp} is a deletion of proximal chromosome 17, it was inferred that sex reversal in mice inheriting the mutation

was caused by hemizygous expression of a gene on the undeleted copy of chromosome 17. The gene was called *Tas*, for *T-associated sex reversal*. Since XYd and *Tas*-mediated XY sex reversal both occur when an *M. m. domesticus* Y chromosome is introduced into the B6 genetic background, it was asked whether they might be related conditions.

Other forms of XY sex reversal XY females have also been generated by deletion of *Sx1* repeat sequences in the mouse Y chromosome. In those cases, *Srγ* is intact but its expression may be altered, suggesting the possibility of long-range position effects.

6.2 XY True Hermaphrodites in the Human

Among the 195 true hermaphrodites surveyed by Willem van Niekerk, 24 (12.3%) had the 46,XY karyotype. Of those, 13 had an ovary on one side of the body and a testis on the other; the other 11 had at least one ovotestis. The mosaic phenotype of the true hermaphrodite (testis versus ovary, in different gonads or in the same gonad), implies mosaic expression of the testis inducer, and this has been borne out by molecular analysis of the *SRY* gene.

The subject of one study was a newborn baby with ambiguous external genitalia and 46,XY karyotype. The gonads were described as ovotestes that contained tubules, Sertoli cells, spermatogonia, and oocytes. There were no Leydig cells and no intact follicles. DNA was extracted from white blood cells and gonadal tissue, and the *SRY* conserved motif was amplified in the PCR. When the PCR products were sequenced, no mutation was found in *SRY* from the white blood cells, but two mutations were found in gonadal tissue. One, a ''silent'' mutation, resulted in a T→C transition in the third nucleotide of codon 22, but there was no change in the amino acid (alanine). The other, a T→A transversion in the second nucleotide of codon 44, induced an amino acid substitution of histidine for leucine. Neither mutation was identified in DNA from the patient's father.

The two mutations that were not identified in all samples of gonadal tissue of the patient serve to confirm mosaic expression of the *SRY* testis inducer, and to explain development of the abnormal gonad in this case. Because the two mutations occurred together in the same cells, it was inferred that they had been induced simultaneously by a mutagen. In fact the mother had worked with organic solvents during early pregnancy.

7 Summary and Conclusions

The function of the human Y chromosome was debatable as recently as 1959, when a number of publications appeared showing that it determines sex. By 1990, the Y-chromosomal testis-determining gene had been cloned, and soon thereafter a comprehensive Y-deletion map containing 132 loci and 43 ordered intervals was produced; each interval was defined by chromosomal breakpoints and contained less than 800 kb of DNA.

By the year 2000, several additional sex-determining genes were identified: the X-linked sex-reversing *DAX1* gene, and the SRY-related *SOX9* gene on chromosome 17q. Another sex-reversing gene *(SF1)* was indicated on chromosome 9. And in keeping with its presumptive role as a transcription factor, the SRY protein was

found to recognize and bind a particular DNA sequence, 5′-AACAAAG-3′.

These findings are consistent with the notion that maleness is the end result of a cascade of events governed by a pathway of sex-determining genes. It is generally held that *SRY* is the initiator of the cascade. But *Sry* of the mouse is transcribed between 9.5 and 12.5 days of gestation (the mouse testis appears at 11.5 days). This implies that *Sry* itself is regulated or ''turned on'' by another gene or group of genes.

In any case, *SOX9* is activated early in the developing testis, indicating that *SOX9* is an early, and perhaps the first, downstream target of *SRY*. Besides *SOX9*, other genes in the pathway have been identified and are being analyzed – notably *DAX1*, *SF1*, *WT1*, and *WNT-4* (discussed in Sects. 3.3, 4.2, 4.3). *SF1* may participate in the development of the indifferent embryonic gonad (which first appears as an outcropping in the coelomic epithelium). The precise sex-determining roles of *WT1* and *WNT-4* remain to be elucidated.

Yet significant advances are being made in our understanding of the heretofore enigmatic conditions of sex reversal. For example, duplication of *SOX9* can ''energize'' the sex-determining cascade in the absence of *SRY*, giving rise to XX testes, and duplication of *DAX1* can block the *SRY* gene, causing aberrant ovarian development in women with XY gonadal dysgenesis. As for the future, we can look forward to a time when the genetics of sex determination will be more thoroughly understood, when many of the syndromes of human sex reversal will be identified and perhaps even corrected prenatally, and when the gender of important domestic species will be placed under absolute control.

Keywords

Cell Adhesion Molecules
Surface ligands, usually glycoproteins, that mediate cell to cell adhesion. Their functions include the assembly and interconnection of various vertebrate systems, as well as maintenance of tissue integration, wound healing, morphogenic movements, cellular migration, and metastasis.

Cell Cycle Regulators
Proteins that regulate the cell division cycle. This family of proteins involves a wide variety of classes, including cyclin-dependent kinases, mitogen-activated kinases, cyclins, and phosphoprotein phosphatases as well as their putative substrates, such as chromatine-associated proteins, cytoskeletal proteins, and transcription factors.

Cytokines
Polypeptides secreted by inflammatory leukocytes, macrophages and lymphocytes in response to microbes and other antigens that mediate and regulate immune and inflammatory reactions. They generally act locally in a paracrine or an autocrine manner rather than in an endocrine manner.

Growth Factors
Signal molecules that act to control cell growth and differentiation in the receptor-dependent fashion. The alterations of these proteins lead to transformation and the accompanying loss in growth control. Some of the growth factors and their receptors are involved in the products of oncogens.

Oncogenes
Genes that can convert cells to cancerous growth by attacking crucial cellular machinery. They encode for growth factors, growth-factor receptors, protein kinases, signal transducers, nuclear phosphoproteins, and transcription factors. These genes are constitutively expressed after structural and /or regulatory changes, resulting in uncontrolled cell proliferation. They can be classified into viral oncogenes (v-oncogenes) and cellular oncogenes (proto-oncogenes).

Telomerase
Essential ribonucleoprotein reverse transcriptase that adds telomeric DNA to the ends of eukaryotic chromosomes. Telomerase is expressed in the testis and ovary, but repressed in normal human somatic tissues. Telomerase activity is seen in more than 90% of human cancers.

Tumor-suppressor Genes
Genes inhibit expression of the tumorigenic phenotype. They are normally involved in holding cellular growth in check. When tumor-suppressor genes are inactivated or lost, a barrier to normal proliferation is removed, leading to unregulated growth.

A large number of molecular events are involved in the development and progression of gastrointestinal carcinomas. Among them, common and distinct events of genetic and epigenetic alterations in oncogenes, tumor-suppressor genes, cell adhesion molecules, DNA repair genes, and genetic instability as well as telomerase activation are observed in esophageal, gastric, and colorectal cancers. In gastric cancer, the pattern of genetic and epigenetic alterations also differs depending on the two histological types, intestinal type or well-differentiated type and diffuse type or poorly differentiated type, indicating that there are two distinct major genetic pathways for gastric carcinogenesis.

In addition to these events, gastrointestinal cancer cells express a broad spectrum of the growth factor/cytokine receptor systems that organize complex cancer-stromal interaction, which confer cell growth, apoptosis, morphogenesis, angiogenesis, progression, and metastasis. However, these abnormal growth factor/cytokine networks also are different among esophageal, gastric, and colorectal cancers, respectively. Importantly, NF-κ**B** activation induced by inflammation may act as a key player for induction of growth factor/cytokine network in gastrointestinal cancers.

1 Introduction

Multiple genetic and epigenetic alterations in oncogenes, tumor-suppressor genes, cell cycle regulations, cell adhesion molecules, DNA repair genes and genetic instability as well as telomerase activation are responsible for the multistep process of human gastrointestinal carcinogenesis. However, a scenario or particular combination of these alterations differs in esophageal, gastric, and colorectal cancers. Namely, common and distinct molecular events are observed in esophageal, gastric, and colorectal cancers, respectively. Moreover, two types of gastric cancer, well-differentiated or intestinal type, and poorly differentiated or diffuse-type carcinomas also exhibit a distinct pattern of genetic pathways.

Besides these genetic and epigenetic events, gastrointestinal cancer cells express a broad spectrum of growth factors, cytokine or both, including epidermal growth factor (EGF) family, transforming growth factor (TGF)-β, heparin binding (HB)-EGF, PDGF, IGF, basic fibroblast growth factor (FGF), interleukin (IL)-1α, IL-6, IL-8 and osteopontin (OPN). These growth factors and cytokines act as autocrine, paracrine, and juxtacrine modulators of the growth of cancer cells, and then organize complex interplay between cancer cells and stromal cells, which plays an important role in cell growth, apoptosis, morphogenesis, angiogenesis, progression and metastasis. Interestingly, the expression of these growth factors, cytokines or both by cancer cells is also different among esophageal, gastric, and colorectal cancers.

This article will provide an overview of the molecular machinery that underlies gastrointestinal carcinogenesis and focuses on abnormal growth factor/cytokine network in gastrointestinal cancers.

2 Genetic and Epigenetic Alterations and Abnormal Growth Factor/Cytokine Network in Esophageal Cancer

Esophageal cancer is the third most frequent gastrointestinal cancer in the world. The most recent estimates are that esophageal cancer is the sixth most common cancer in men (212 600 new cases, 4.9% of all cancers) and the ninth most common in women (103 200 new cases, 2.7% of all cancers). The two main histological types of esophageal cancer are squamous cell carcinoma (SCC) and adenocarcinoma, but SCC is the more prevalent type worldwide. The development of esophageal SCC exhibits a multistep, progressive process. An early indicator of this process is an increased proliferation of esophageal epithelial cells including basal cell hyperplasia, dysplasia, and carcinoma *in situ*. This multistep process requires the accumulation of multiple genetic and epigenetic alterations and overexpression of growth factors/cytokine receptor systems, leading to the evolution of clonal cell populations that possess growth advantages over other cells as demonstrated in the progression model of head and neck cancer. This paragraph thus will describe recent advances in molecular dissection of multistep tumorigenesis of esophageal SCC and abnormal growth factor/cytokine network that contributes to the development and progression of esophageal SCC.

2.1 Genetic and Epigenetic Alterations in Esophageal SCC

Numerous genetic and epigenetic alterations are implicated in the development and progression of esophageal SCC (Table 1). This cancer is frequently associated with loss of heterozygosity (LOH) at multiple chromosomal loci including 3p, 5q, 9p, 9q, 13q, 17p, 17q, and 18q. No significant differences have been found in the prevalence of LOH at various loci in SCC and adenocarcinoma of the esophagus.

Tab. 1 Genetic and epigenetic alterations found in esophageal SCC.

Genetic and epigenetic alterations	*Incidence [%]*
Tumor suppressors	
P53 LOH, mutation	40–60
APC LOH	60–70
DCC LOH	20–40
Rb LOH	40–50
BRCA1 LOH	60
3p LOH	40–100
5p LOH	62
9p LOH	45–76
9q LOH	60
13q LOH	57
14q LOH	65
17p LOH	43–65
17q LOH	62
RARβ2 loss	40–50
Cell cycle regulators	
p16 loss, mutation	45–76
Cyclin D_1 amplification	40–50
Oncogenes	
EGFR amplification	10–15
Telomerase activity	86
TERT expression	96

Among these alterations, LOH and mutation of the *p53* gene at chromosome 17p13 occur at an early stage of esophageal carcinogenesis, such as dysplasia and carcinoma *in situ*. About 50% of esophageal SCC harbor mutations of the *Tp53* gene, most of which are missense mutations leading to amino acid changes within exons 5–8, which encode the entire DNA binding domain of the p53 molecule and the flanking splice sites. Considering the

base substitution spectrum, G:C to T:A transversion is common in esophageal carcinoma, similar to that in carcinomas of the lung and liver. This situation is different from the finding that colorectal carcinomas frequently contain G:C to A:T transitions at CpG dinucleotides. This evidence suggests that different environmental and intrinsic factors may affect the tumorigenesis of esophageal and colorectal carcinomas. It is of interest that LOH of the *APC, DCC*, and *Rb* genes shows high frequency but these genes are very rarely or never mutated in esophageal SCC.

The retinoic acid receptor (RAR) β gene is a putative tumor-suppressor gene on chromosome 3p24, where a high frequency of LOH is found in many human cancers, including esophageal cancer. The human RARβ has three isoforms (β1, β2, β4). Overexpression of RARβ2 induces inhibition of tumor cell growth and apoptosis in human cancer cell lines including esophageal cancer cells. Moreover, Induction of RARβ2 suppresses cyclooxygenase-2 (COX2) expression in esophageal cancer cells. More importantly, DNA methylation of RARβ2 promoter CpG sites has been reported to cause the loss of RARβ2 expression in many human cancers including lung, breast, prostate, stomach, head and neck, and esophageal cancers. RARβ is expressed in 90% of normal esophageal mucosa, while it is detected in only 60% of dysplastic lesions and in 50% of SCC. These findings indicate that loss of RARβ, or more specifically, the isoformβ2, is an early event associated with esophageal carcinogenesis and the status of squamous differentiation.

p16, an inhibitor of cyclin D1/cyclin-dependent kinase, is located on chromosome 9p21. It is inactivated by 9p21LOH with *de novo* p16 promoter hypermethylation in the majority of esophageal SCC. Recent molecular analysis of precancerous laryngeal lesions suggests that loss of p16 protein is an early step toward malignant transformation in head and neck tissues. This protein forms binary complexes with CDK4 and CDK6, inhibiting their ability to phosphorylate the Rb protein. Loss of the p16 protein may bring about increased Rb phosphorylation and allow cells to enter into S-phase. In fact, we have confirmed that homozygous deletion of the *p16* gene is closely correlated with the increased expression of cyclin D1, CDK4 and phosphorylated Rb protein in esophageal SCC cell lines.

In 1989, we discovered the coamplification of *hst-1* and *int-2*, both of which are located on chromosome 11q13, in about 50% of primary tumors and in 100% of metastases of esophageal SCC. Gene amplification, however, was not accompanied by overexpression of the two genes. Subsequently, Jiang et al. found that the cyclin D1, which is located on the same locus as *hst-1* and *int-2* genes, was amplified in 32% of SCC, associated with overexpression. The amplification of the cyclin D1 is closely correlated with tumor staging, depth of tumor invasion, and metastasis. In the esophagus, 71% of SCC and 64% of adenocarcinoma are positive for increased cyclin D1 nuclear staining, indicating that overexpression of cyclin D1 is common in both types of cancer. Cyclin D1 binds to Rb protein and stimulates its phosphorylation. Hyperphosphorylation of Rb in response to overexpressed cyclin D1 may lead to uncontrolled cell cycling and increased cell proliferation.

As for oncogene activation, amplification of the EGF receptor (*EGFR*) gene occurs in 10–15% of advanced cases of

esophageal SCC, accompanied by overexpression of EGFR. The frequency of K-ras mutation is very low in esophageal SCC, whereas it takes place in 50% of sporadic colorectal carcinoma. c-*erb*B2 is amplified in esophageal adenocarcinoma but not in esophageal SCC. Recently, Inazawa's group reported that *ZASC1* encoding a Krüppel-like zinc finger protein is involved in the pathogenesis of esophageal SCC as one of the targets for 3q26 amplification. *CIAP1*, a number of the *IAP* (antiapoptotic) gene family, may also be a target for 11q22 amplification.

Telomerase, a ribonucleoprotein enzyme, is necessary for cancer cells to maintain their telomere and to become immortal. Results of a 1998 study on cell immortalization show, however, that activation of telomerase alone is not enough to immortalize certain epithelial cells, and that inactivation of the p16/Rb pathway is needed. More than 80% of gastrointestinal carcinomas exhibit high level of telomerase activity and overexpression of human telomerase reverse transcriptase (hTERT). The expression of hTERT is closely associated with activation of telomerase *in vitro* and *in vivo*. It is of interest to note that telomerase activity as well as hTERT expression is detected in about 45% of dysplasia and in 90% of SCC of the esophagus. Telomerase activation may also play a critical role in early stage of esophageal SCC.

Recently, Chen et al. reported that LOH at 13q 33–34 including *ING1*, a candidate tumor-suppressor gene, was observed in about 60% of esophageal SCC, associated with mutation as well as loss of ING1 protein. ING1, a novel growth inhibitor, cooperates directly with p53 in growth regulation by modulating the ability of p53 to act as a transcriptional activator. Genetic or epigenetic alterations in ING1 may be also involved with esophageal SCC. Sonoda et al. reported that loss of *LRP1B* (low density lipoprotein receptor–related protein 1*B*) often occurs in esophageal SCC.

These results overall indicate that accumulation of the above-mentioned genetic and epigenetic alterations is involved in the multistep carcinogenesis and progression of esophageal SCC. Inactivation of tumor-suppressor genes on 3p (ex. RARβ2) and p53, and telomerase activity may be important for converting normal stratified squamous epithelium to dysplasia. Because p16 inactivation and 9q LOH are found occasionally in mild dysplasia, but frequently in severe dysplasia and in carcinoma *in situ*, these alterations may have implications for transformation to malignancy. Amplification of cyclin D1and *EGFR* genes, inactivation of tumor-suppressor genes on 5q, 13q, and 18q, and abnormal expression of growth factor/cytokine receptor system may confer progression and metastasis of esophageal SCC. The genetic progression model of esophageal SCC (Fig. 1) is quite similar to that of head and neck SCC

2.2 Abnormal Growth Factor/Cytokine Network in Esophageal SCC

Esophageal SCC cells express a variety of growth factor/ receptor and cytokines including the EGF family, PDGF, transforming growth factor β (TGFβ), interleukin (IL)-1α and IL-6. Among them, the EGF/TGFα receptor system plays a major role in the cell growth and progression of esophageal SCC through signaling of receptor-linked tyrosine kinases.

In many cancer cells, both EGF and TGFα act as autocrine growth factors through EGFR which is encoded by the proto-oncogene *c-erbB1*.

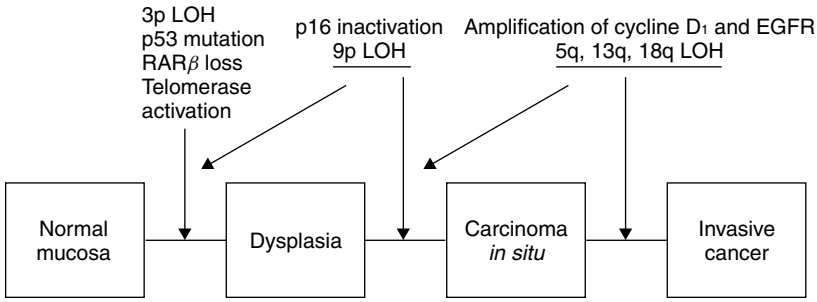

Fig. 1 Genetic progression model of esophageal SCC.

Membrane-bound TGFα binds to EGFR on the surface of contiguous cells and induces receptor autophosphorylation, leading to signal transduction, which is regarded as juxtacrine mitogenetic stimulation. In addition, EGF or TGFα induce the expression of TGFα and EGFR, thus indicating the presence of an autocrine loop of EGF/TGFα/receptor system. We have found that EGF is expressed in 30% of esophageal SCC while TGFα and EGFR are expressed in 77 and 89% of esophageal SCC, respectively. Coexpression of TGFα and EGFR is closely correlated with dysplastic progression and high grade of malignancy. The number of EGFR receptors is about 10 times higher than that in gastric carcinomas, which might be one of the reasons for the rapid growth of esophageal SCC compared to that of other carcinomas.

Esophageal SCC expresses PDGF A- and B-chains and PDGF B-receptor, suggesting the existence of a multiautocrine loop in the growth and progression of tumor cells. What is interesting is that EGF or TGFα increase the expression of PDGF A- and B-chain in esophageal SCC cell lines.

Grb7, a ligand for both EGFR and c-*erb*B2, is also implicated in esophageal SCC. Tanaka et al. found overexpression of Grb7in 44 % of the tumors and coexpression of Grb7 with EGFR or c-*erb*B-2 in 32% of the advanced cases, suggesting that Grb7 functions as an extracellular stimulus for progression of esophageal SCC.

EGF or TGFα produced by the tumor cells can make not only an autocrine loop of EGF/TGFα receptor system for tumor growth stimulation but also an induction of matrix metalloproteinases such as intestinal collagenase and stromelysin to evoke a cascade of cellular events that are involved in extracellular matrix degradation and tumor invasion. Moreover, one of the important substrates of EGFR kinase is β-catenin, a regulatory protein for cadherin. Upon phosphorylation of β-catenin, the cells are dissociated by loss of cadherin function. A phosphorylated form of β-catenin is detected in tumor cells of esophageal SCC and adenocarcinomas. β-catenin is also involved as a downstream transcriptional activator of the Wnt signaling pathway. Recently, β-catenin has been shown to induce cyclin D1 expression, suggesting that free β-catenin may be implicated in an increase in cell cycling.

In addition to phosphorylation of β-catenin, downregulation of E-cadherin and α-catenin occurs in both esophageal SCC and adenocarcinomas, while upregulation of P-cadherin takes place in

esophageal SCC. The reduced expression of α-catenin correlates more with invasion and nodal metastasis than E-cadherin reduction in esophageal SCC.

Above all, esophageal SCC exhibit multiple autocrine growth factor-receptor loops that may participate not only in cell growth but also in tumor invasion and metastasis, associated with reduction of cell adhesion molecules. Understanding the biology of esophageal cancer is indispensable to precise diagnosis and proper cancer treatment.

3 Genetic and Epigenetic Alterations and Abnormal Growth Factor/Cytokine Network in Gastric Cancer

Gastric cancer is the most common cancer worldwide and is second only to lung cancer as a cause of cancer mortality. Most recent world estimates indicate that 798 000 new cases are diagnosed and 628 000 deaths occur annually from gastric cancer. The highest incidence is still observed in Japan because of the remarkable increase in the aged population over 60 years old. Most gastric cancers arise distally from the antrum and pylorus, but about 20% involve the cardia and fundus and approximately 10% involve the stomach diffusely.

There are several histological classifications of gastric cancer. Lauren divided gastric cancer into two types, intestinal and diffuse, and the Japan Research Society for Gastric Cancer classified it into five common types. The JRSGC classification is similar to that of the World Health Organization. This article will use a two-type classification: the intestinal or well-differentiated type and the diffuse or poorly differentiated type.

The genetic and epigenetic changes found in gastric carcinoma differ depending on the histological type of gastric cancer, indicating that different carcinogenetic pathways exist for the intestinal and diffuse types of carcinomas. In addition, cancer-stromal interaction through the growth factor/cytokine receptor system, which plays a pivotal role in morphogenesis, cancer progression, and metastasis, is also different between the two types of gastric carcinomas.

Meta-analysis of epidemiological studies and animal models show that both intestinal and diffuse types of gastric cancer are equally associated with *Helicobacter pylori* (*H. pylori*) infection. However, *H. pylori* infection may play a role only in the initial steps of gastric carcinogenesis. Differences in *H. pylori* strain, patient age, exogenous or endogenous carcinogens and genetic factors such as DNA polymorphism and genetic instability may be implicated in two distinct major genetic pathways for gastric carcinogenesis.

The next paragraph will describe the genetic pathways of the two types of gastric cancer and the abnormal growth factor/cytokine network that organizes remarkably complex interplay between cancer cells and stroma cells in gastric cancer.

3.1 Genetic and Epigenetic Alterations in Gastric Cancer

Genetic and epigenetic alterations in oncogenes, tumor-suppressor genes, cell-cycle regulators, cell adhesion molecules, DNA repair genes, and genetic instability as well as telomerase activation, are responsible for tumor genesis and progression of gastric cancer (Tables 2 and 3; Figs. 2 and 3). Among them, inactivation of various genes including *p16*, *hMLH1*, cadherin1(*CDH1*),

Tab. 2 Genetic and epigenetic alterations found in intestinal and diffuse types of gastric cancer (1).

Genetic and epigenetic alterations	***Incidence of cases with indicated alterations [%]***

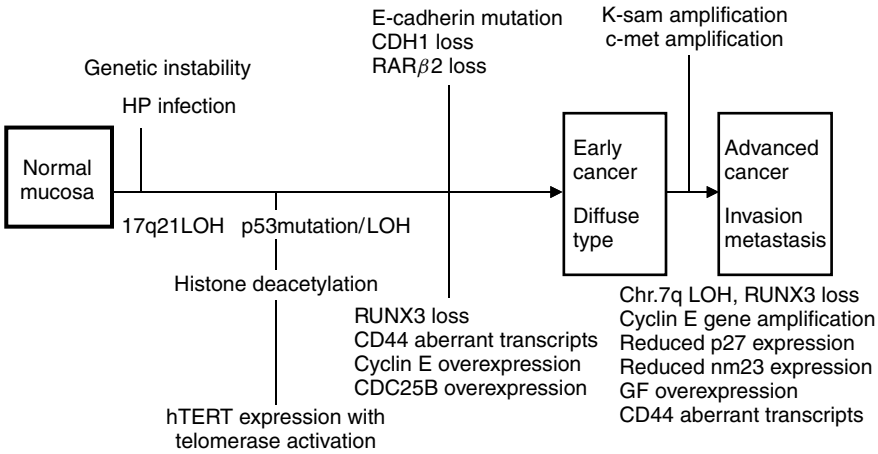

Fig. 3 Multiple genetic and epigenetic alterations during human gastric carcinogenesis (diffuse type).

RARβ2, *pS2* and *RUNX3* by DNA methylation is involved in two distinct major genetic pathways of gastric cancer. Hypermethylation of the p16 and of hMLH1 promoters is preferentially associated with intestinal type, whereas concordant hypermethylation of the CDH1 and RARβ2 promoters predominantly occurs in diffuse type gastric carcinoma. Loss of RUNX3 and pS2 expression by promoter methylation is a common event in both types of gastric carcinoma. The scenario of these epigenetic alterations indicates that there are at least two types of CpG island methylator phenotypes in intestinal and diffuse types of gastric cancer. Recently, Cho et al. reported that promoter hypomethylation of a novel cancer/testis antigen gene CAGE was found in 35% of chronic gastritis and in 78% of gastric cancer.

In addition to promoter hypermethylation or hypomethylation, acetylated histone H4 is obviously reduced in the majority of gastric carcinoma. Histone H4 is progressively deacetylated from the early stage (precancerous lesions) to the late stage (invasion and metastasis) in gastric carcinogenesis. Since there is no difference in the level of acetylated histone H4 between the intestinal and diffuse types of gastric cancer, histone H4 deacetylation is a common event in both types of gastric cancer.

In the multistep process of intestinal type carcinogenesis, the genetic pathways can be divided into three subways: an intestinal metaplasia → adenoma → carcinoma sequence, an intestinal metaplasia → carcinoma sequence and *de novo*. Infection with *H. pylori* may be a strong trigger for hyperplasia of hTERT-positive ''stem cell'' in intestinal metaplasia. Genetic instability and hyperplasia of hTERT positive stem cells precede replication error at the D1S191, DNA hypermethylation at the D17S5 locus, pS2 loss, RARβ2 loss, RUNX3 loss, CD44 abnormal transcripts and p53 mutation, all of which accumulate in at least 30% of incomplete intestinal metaplasia. All of these epigenetic and genetic changes are common events in intestinal type gastric cancer. An adenoma → carcinoma sequence is found in about 20% of gastric adenoma with APC mutations. In addition to these events, p53 mutation and LOH, RUNX3 loss, reduced p27 expression, cyclin E overexpression and abnormal transcript of c-met allow malignant transformation from the above precancerous lesions to intestinal type gastric carcinoma (Fig. 2). DCC loss, APC mutations, 1qLOH, p27 loss, reduced TGFβ receptor, reduced *nm23* and *c-erbB2* gene amplification are frequently associated with an advanced stage of intestinal-type gastric carcinoma. The *de novo* gastric carcinoma involves LOH and abnormal expression of *p73* gene that is responsible for the development of foveolar-type gastric cancers with pS2 expression.

On the other hand, LOH at chromosome 17p, mutation or LOH of p53, LUNX3 loss, and mutation or loss of E-cadherin are preferentially involved in the development of diffuse type gastric carcinoma. These events may occur simultaneously or in the relatively short term in superficial gastritis induced by *H. pylori* infection. In addition to these alterations, gene amplification of *K-sam* and *c-met*, RUNX3 loss, 7q LOH, cyclin E gene amplification, p27 loss as well as reduced nm23 confer progression, and metastasis, frequently associated with productive fibrosis. Mixed gastric carcinomas composed of intestinal and diffuse components exhibit some but not all of the molecular events described

so far for each of the two types of gastric cancer (Fig. 3).

Several proto-oncogenes, including *c-met, K-sam*, and *c-erbB2*, are frequently activated in gastric cancer. The amplification of the *c-met* gene encoding a receptor for hepatocyte growth factor/scatter factor (HGF/SF) is found in 19% of intestinal type and 39% of diffuse type gastric cancers. Most of gastric carcinomas express two different c-met transcripts, one of 7.0 kb and another of 6.0 kb. Expression of the 6.0 kb c-met transcript correlates well with tumor staging, lymph node metastasis, and depth of tumor invasion. The *K-sam* gene has at least four transcriptional variants. Type II transcript, which is expressed only in carcinoma cells, encodes a receptor for keratinocyte growth factor (KGF). *K-sam* is preferentially amplified in 33% of advanced diffuse or scirrhous type gastric cancer. But *K-sam* gene amplification is never seen in esophageal or colorectal carcinomas. In contrast to *K-sam, c-erbB2* is preferentially amplified in 20% of intestinal type gastric cancer but not in diffuse type gastric cancer. Overexpression of *c-erbB2* associated with gene amplification confers a poor prognosis and liver metastasis. The amplification of *c-erbB1* (EGFR) and *c-erbB3* is seen in 3 and 0%, respectively, of gastric cancer.

RUNX3, a Runt domain transcription factor involved in TGFβ signaling, is a candidate tumor-suppressor gene localized in 1p36, a region commonly deleted in a variety of human cancers, including gastric cancer. *RUNX* gene family is composed of three members, *RUNX1/AML1, RUNX2* and *RUNX3*, and encodes the DNA binding(α) subunits of the Runt domain transcription factor polyomavirus enhancer-binding protein 2 (PEBP2)/core-binding factor (CBF), which is a heterodimeric transcription factor. All three *RUNXs* play important roles in both normal developmental processes and carcinogenesis. *RUNX1*, which is required for definitive hematopoiesis, is the target of chromosome translocations in leukemia. *RUNX2*, which is essential for osteogenesis, is mutated in the human disease cleidocranial dysplasia. *RUNX3* is necessary for the suppression of cell proliferation of gastric epithelium, neurogenesis of the dorsal root ganglia, and T-cell differentiation. The gastric epithelium of RUNX3 knockout mice shows hyperplasia, reduced rate of apoptosis, and reduced sensitivity to TGFβ1, suggesting that the tumor-suppressor activity of RUNX3 operates downstream of the TGFβ signaling pathway.

Recent studies on RUNX3 methylation in human cancers demonstrated that loss of RUNX3 by hypermethylation of the promoter CpG island was detected not only in 64% of gastric cancer but also in 73% of hepatocellular carcinoma, 70% of bile duct cancer, 75% of pancreatic cancer, 62% of laryngeal cancer, 46% of lung cancer, 25% of breast cancer, 23% of prostate cancer, 12% of endometrial cancer, 2.5% of uterine cervical cancer, and 5% of colon cancer. The RUNX3 methylation is especially frequent in cancers from tissues of a foregut origin. Interestingly, the RUNX3 methylation is found in 8% of chronic gastritis, 28% of intestinal metaplasia, and 27% of gastric adenoma, but not in chronic hepatitis B. These findings suggest that RUNX3 is a target for epigenetic gene silencing in gastric carcinogenesis.

Cell adhesion molecules may also work as tumor suppressors. Mutations in the E-cadherin gene occur preferentially in 50% of diffuse type gastric carcinoma. E-cadherin mutations affecting exons 8 or 9 induce the scattered morphology, decreased cellular adhesion and increased

cellular motility of diffuse gastric cancers. The mutations are even detected in intramucosal carcinoma. E-cadherin germline mutations responsible for hereditary diffuse gastric cancer (HDGC) have been reported since 1998, but their frequency is extremely rare. The β- and γ-catenin mutations but not E-cadherin mutations bring about constitutive Tcf transcriptional activity in gastric and pancreatic cancer cells. As mentioned in esophageal SCC, cross-talk between β-catenin and receptor tyrosine kinases including c-met, EGFR and c-*erb*B2 is found in gastric cancer cells, leading to diffuse spreading or scattering of gastric cancer cells through enhanced Wnt signaling pathway. These results indicate that genetic and epigenetic alterations in E-cadherin and catenins are involved in the development and progression of diffuse and scirrhous-type gastric cancer.

As to alterations in cell-cycle regulators, the cyclin E gene is amplified in 15 to 20% of gastric carcinomas that are associated with overexpression. Gene amplification or overexpression of cycline E, or both cause aggressiveness and lymph node metastasis. Cyclin D1 gene amplification, on the other hand, is exceptional in gastric cancer but frequently occurs in esophageal SCC. p27, a member of the cip/kip family of CDK inhibitors, binds to a wide variety of cyclin/CDK complexes and inhibits kinase activity. We have found that growth suppression of interferon-β is associated with the induction of p27 in the gastric cancer cell line TMK-1. More importantly, reduction in p27 expression is frequently observed in advanced gastric cancers while it is well preserved in 90% of gastric adenomas and 85% of early cancers. Reduced expression of p27 significantly correlates with tumor invasion and nodal metastasis. The expression of p27 in gastric cancer is inversely correlated with the expression of cyclin E. Loss of p27 expression and gain of cyclin E promotes progression and metastasis of gastric cancer.

Reduction in p27 occurs at posttranslational levels, resulting from ubiquitin mediated proteosomal degradation rather than genetic abnormalities.

An important downstream target of cyclin/CDKs at G1/S transition is a family of E2F transcription factors. Gene amplification of E1F-1 is seen in 4% of gastric cancers and in 25% of colorectal cancers. Overexpression of *E2F* is detected in 40% of primary gastric carcinomas. In addition, E2F and cyclin E tend to be coexpressed in gastric cancer, whereas 70% of gastric cancers show lower levels of E2G-3 expression than corresponding normal mucosa. These results overall suggest that gene amplification and abnormal expression of the *E2F* gene may permit the development of gastric cancer.

3.2 Factors Associated with Increased Incidence of Gastric Cancer

Three major factors, including environmental factors, host factors and genetic factors, cooperatively affect the genesis of gastric cancer. Of these, environmental factors are the most important, as diet and cigarette smoking are primary offenders; in particular, the presence of carcinogens such as *N*-nitroso compounds and benzo[α]pyrene is directly linked to carcinogenesis. The mutation spectrum of the *p53* gene is different between intestinal type and diffuse type gastric cancers, as p53 mutation at A:T sites are common in intestinal type carcinoma whereas GC $\rightarrow$ AT transitions are predominant in diffuse type carcinoma. Carcinogenic *N*-nitrosoamines, which cause mainly GC $\rightarrow$ AT base substitutions, are found in many

foods and can also be produced from amines and nitrates in the acidic environment of the stomach.

As for host factors, meta-analysis of relationship between *H. pylori* infection and gastric cancer has indicated that *H. pylori* infection is associated with a twofold increased risk of gastric cancer. Younger *H. pylori* infected patients have a higher relative risk of gastric cancer than older patients. *H. pylori* infection is equally associated with intestinal-type and diffuse-type gastric cancers. In fact, the observations in a Mongolian gerbil model of stomach carcinogenesis show that *H. pylori* infection promotes stomach carcinogenesis induced by chemical carcinogens, and that histological types of gastric carcinoma may depend on the concentration of chemical carcinogens rather than *H. pylori* infection. Eradication of the bacteria evidently decreases the incidence of gastric cancer in the Mongolia gerbil model.

H. pylori infection produces reactive oxygen and nitrogen species that cause DNA damage, followed by chronic gastritis and intestinal metaplasia. Goto et al. reported that the expression of inducible nitric oxide synthase (iNOS) and nitrotyrosine in the gastric mucosa was significantly high in *H. pylori* infected patients who developed gastric cancer at least two years after the initial biopsies. These findings suggest that high production of iNOS and nitrotyrosine may participate in gastric carcinogenesis.

Not only can *H. pylori* activate NF-κB in gastric epithelial cells, but activated NF-κB activates the transcription of IL-1, IL-6, IL-8, TNF-α, and cyclooxygenase-2 (Cox-2). Successful eradication of *H. pylori* leads to downregulation of Cox-2 in the epithelial and stromal cells. High expression of Cox-2 mRNA, protein, and enzymatic activity is observed in the tumor cells of intestinal type gastric cancer. Loss of Cox-2 promoter methylation may enhance Cox-2 expression and promote gastric carcinogenesis associated with *H. pylori*.

Strain of *H. pylori* and genetic factors play a critical role in susceptibility to stomach carcinogenesis. Prinz et al. reported that CagA+/VacAs1+ strains of *H. pylori* that are blood-group antigen-binding adhesion (BabA2)-positive are associated with activity or chronicity of gastritis. Adherence of *H. pylori* via BabA2 may play a key role for efficient delivery of VacA and CagA. Moreover, Hatakeyama's group has recently shown that CagA binds an Src homology 2 (SH2)-containing tyrosine phosphatase SHP-2 in a tyrosine phosphorylation-dependent manner and stimulates the phosphatase activity of SHP-2. In addition, they found that prevalent CagA protein in East Asian countries are significantly more potent in binding SHP-2 and in inducing cellular morphological changes than are CagA proteins of Western isolates. Differences in the biological activity of Western and East Asian CagA protein, which are determined by variation in the tyrosine phosphorylation sites, may underlie the different incidences of gastric cancer in these two geographic areas. Regarding the development of gastric mucosa-associated lymphoid tissue (MALT) lymphoma, heat-shock protein 60 kDa (hsp60) of *H. pylori* is an important antigen in the pathogenesis of MALT lymphoma.

In addition to *H. pylori* strains, DNA polymorphism including HLA, MUC1, T-cell helper 1 and IL-1β has been reported to be associated with an increased risk of both atrophic gastritis induced by *H. pylori* and gastric cancer. In addition, El-Omar et al. reported that proinflammatory genotypes of tumor necrosis factor α and IL-10 are associated with increased risk

of gastric cancer. More excitingly, Magnusson et al. found that distinct HLA class IIDQ and DR alleles are associated with the development of gastric cancer and infection with *H. pylori*. The DQA1*0102 is associated with protection from *H. pylori* infection, whereas the DRB*1601 is associated with cancer development, particularly, *H. pylori*-negative diffuse type gastric cancer. These host factors as well as *H. pylori* strain may determine why some individual infected with *H.pylori* develop gastric cancer while others do not.

The most important factor implicated in gastric carcinogenesis is genetic instability including microsatellite instability (MSI) and chromosomal instability. MSI due to epigenetic inactivation of the hMLH1 is found in 15 to 39% of sporadic intestinal type gastric cancer, of which 70% are associated with loss of hMLH1 by hypermethylation of the hMLH1 promoter. Intestinal type gastric cancers with MSI often occur in patients over 73 years of age and often occur in the antrum pylori. They are also associated with abundant lymphocyte infiltration, a putative favorable prognosis, and multiple tumors. In addition, MSI at the locus D1S191 is found in 26% of intestinal metaplasia and 46% of intestinal type gastric cancer. An identical pattern of MSI at the locus D1S191 is detected in both intestinal type cancer and the adjacent intestinal metaplasia, suggesting the sequential development of intestinal adenocarcinoma from intestinal metaplasia.

On the other hand, diffuse type gastric cancers with MSI occur mostly in patients under 35 years of age, and are frequently accompanied by scirrhous type carcinoma. This type of cancer, however, harbors no germline mutation of hMLH1 and hMSH2 and no alteration at BAT-RII, but is frequently associated with LOH on chromosome 17q21 including the *BRCA1* gene. Loss of the *BRCA1* by promoter methylation may have implications for the genesis of diffuse type gastric cancer.

Chromosomal instability leading to DNA aneuploidy is also an underlying factor in cancer. Telomere length is necessary for maintaining chromosomal stability. Recent evidence indicates that in the absence of telomerase, telomere shortening can bring about telomere dysfunction that causes both DNA breaks and chromosome gain or loss. Conversely, telomerase can inhibit chromosomal instability. Most intestinal type gastric cancers have remarkably shortened telomere length, associated with high levels of telomerase activity and significant expression of human telomerase reverse transcriptase (hTERT). More importantly, over 50% of intestinal metaplasia, as well as adenoma, express low levels of telomerase activity. We have found that *H. pylori* infection is a strong trigger for hyperplasia of hTERT positive cells in intestinal metaplasia, followed by increased telomerase activity and telomere reduction. Therefore, telomere reduction and telomerase activation play the most critical roles in an initial step of gastric carcinogenesis.

Mutations in the *APC* gene participate in chromosomal instability. Recently Kaplan et al. reported that mutation in *APC* may be responsible for chromosomal instability in colon cancer. It remains to be examined whether gastric cancer cells carrying a truncated *APC* gene are defective in chromosome segregation. APC protein directly binds to a kinetochore protein and is an avid *in vitro* substrate of the mitotic check-point protein Bub1. There

is no mutation in the *hBub1* gene in gastric cancer.

3.3 Abnormal Growth Factor/Cytokine Network in Gastric Cancer

Gastric cancer cells express a broad spectrum or growth factors, cytokines or both, including TGF-α, TGF-β, EGF, amphiregulin (AR), cripto, heparin binding (HB)-EGF, PDGF, IGF II, basic fibroblast growth factor (bFGF), IL-1α, IL-6, IL-8, and OPN. These growth factors and cytokines function as autocrine, paracrine, and juxtacrine modulators for the growth of cancer cells, and they organize the complex interaction between cancer cells and stromal cells which play a key role in morphogenesis, invasion, neovascularization, and metastasis (Fig. 4). Interestingly, the expression pattern of these growth factors and cytokines by cancer cells differs in the two histological types of gastric carcinomas. The EGF family including EGF, TGFα, cripto and AR are commonly overexpressed in intestinal type carcinoma, whereas TGFβ, IGF II, and bFGF are predominantly overexpressed in diffuse type carcinoma. Coexpression of EGF/TGF-α, EGFR and cripto correlates well with the biological malignancy, as these factors induce metalloproteinases. Overexpression

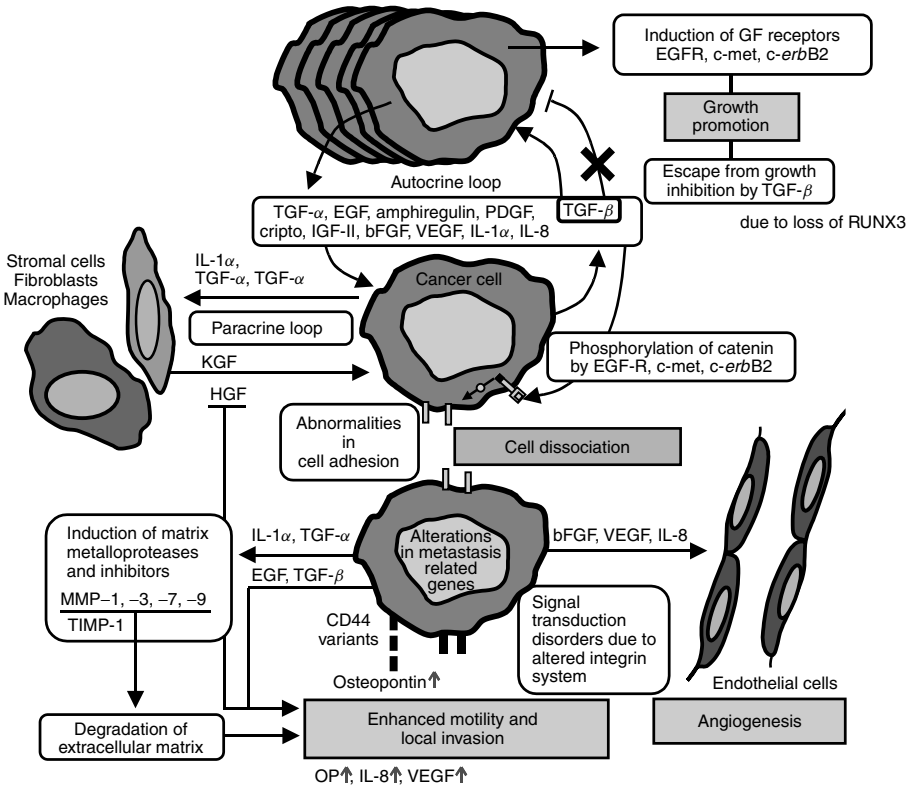

Fig. 4 Cancer-stromal interaction in gastric cancer through growth factors and cytokines.

of cripto is frequently associated with intestinal metaplasia and gastric adenoma. Akagi et al. have recently shown that gastric cancer cells express neutrophilin-1(NRP-1), which acts as a coreceptor for VEGF-165 and increases its affinity for VEGF receptor 2 endothelial cells. EGF induces both NRP-1 and VEGF expression, suggesting that regulation of NRP-1 expression in gastric cancer is intimately associated with EGF/EGFR system.

IL-1α is a cytokine mainly produced by activated macrophages through NF-κB activation and mediates many of the local and systemic responses to infection and inflammation. Gastric cancer cells also produce it. We have found that IL-1α acts as an autocrine growth factor for oral and gastric carcinoma cells and plays a pivotal role as a trigger for induction of EGF and EGFR expression. The expression of IL-1α by tumor cells is induced by either IL-1α, EGF, or TGF-α, while IL-α upregulates the expression of TGF-α and EGFR by tumor cells themselves, indicating that an intimate interplay between IL-1α and EGF/receptor system stimulates the growth of gastric cancer cells. In addition to IL-1α, IL-6 is also an autocrine growth stimulator for gastric cancer cells. The expression of IL-1α by tumor cells is induced by IL-6, while IL-1α increases the expression of IL-6 by tumor cells themselves. Currently, Fukayama's group reported that IL-1β may act as an autocrine growth factor in a human Epstein-Barr virus-associated gastric carcinoma.

IL-8, a member of the CXC chemokine family, induces haptotactic migration and proliferation of melanoma cells and angiogenesis. More importantly, gastric cancer cell lines express mRNA and protein for IL-8 and IL-8 receptors (IL-8RA and IL-8RB). More than 80% of primary tumors coexpress IL-8 and IL-8 receptor; this coexpression correlates directly with tumor vascularity and tumor progression. IL-8 enhances the expression of EGFR, type IV collagenase (MMP-9), VEGF, and IL-8 itself by tumor cells, while IL-8 decreases expression of E-cadherin. Moreover, IL-8 increases MMP-9 activity and the ability of gastric cancer cells to invade through Matrigel. IL-8 may play an important role in the growth and progression of gastric carcinoma by autocrine and paracrine mechanisms.

In addition to IL-8, VEGF and bFGF participate mainly in neovascularization in gastric cancer. We have shown that eight gastric cancer cell lines secrete VEGF into conditioned media. EGF or IL-1α upregulates VEGF expression by tumor cells, whereas interferon-γ downregulates it. VEGF promotes angiogenesis and the progression of gastric carcinoma, especially intestinal type. VEGF-C produced by tumor cells participates in the development of lymph node metastasis. On the other hand, bFGF produced by tumor cells is frequently associated with angiogenesis and extensive fibrosis in diffuse type carcinoma, particularly those of the scirrhous type. Interestingly, Nakazawa et al. reported that keratinocyte growth factor (KGF) produced by gastric fibroblasts specifically binds to K-sam on tumor cells and then stimulates proliferation of cancer cells, resulting in the development of the scirrhous type of gastric cancer. KGF from gastric fibroblasts may underline the remarkable proliferation of scirrhous gastric cancer cells in a paracrine manner.

Stromal cells, especially fibroblasts stimulated by growth factors or cytokines such as IL-1α, TGF-α, and TGFβ, secrete HGF/SF, which can function in a paracrine manner as a morphogen or mitogen of tumor cells. For example, in the case

of a cancer cell clone maintaining expression of cell adhesion molecules, HGF/SF promotes tubular formation of tumor cells, resulting in intestinal type gastric cancer. Conversely, in the case of a clone with reduced expression of cell adhesion molecules, HGF/SF can act as a mitogen and induce scattering of tumor cells, resulting in diffuse type gastric cancer.

OPN, also termed Eta-1 (early T-lymphocyte activation-1), which is a reported protein ligand of CD44, is overexpressed in 73% of gastric cancer. The coexpression of OPN and CD44 v9 in tumor cells correlates with the nodal metastasis in diffuse type gastric cancer. The *CD44* gene contains at least 20 exons, 12 of which can be alternatively spliced to make up a wide variety of molecular variants. All gastric cancer cell lines and primary tumors show overexpression of abnormal CD44 transcripts containing the intron 9 sequence. The intestinal metaplasia also expresses these variants but normal gastric mucosa does not express them. Currently, Medico et al. reported that OPN is an autocrine mediator of HGF induced invasive growth.

4 Genetic and Epigenetic Alterations and Abnormal Growth Factor/Cytokine Network in Colorectal Cancer

Cancer of the colon and rectum is the fourth most common cancer in the world. In 1996, an estimated 875 000 new cases were diagnosed worldwide, accounting for 8.5% of all new cancers. Approximately 98% of malignant colorectal tumors are adenocarcinoma. Rectal tumors account for about 27%, while almost 50% occur proximal to the splenic flexure.

The accumulation of multiple genetic and epigenetic alterations in tumor-suppressor genes, oncogenes and DNA mismatch repair genes takes place in the multistep process of colorectal carcinogenesis. Inactivation of APC, p53, and DCC and K-ras mutations are involved in a major genetic pathway for colorectal tumorigenesis showing the course of malignant progression from normal mucosal cells through adenomas (adenoma–carcinoma sequence) (Fig. 5). This section will make an overview of multiple

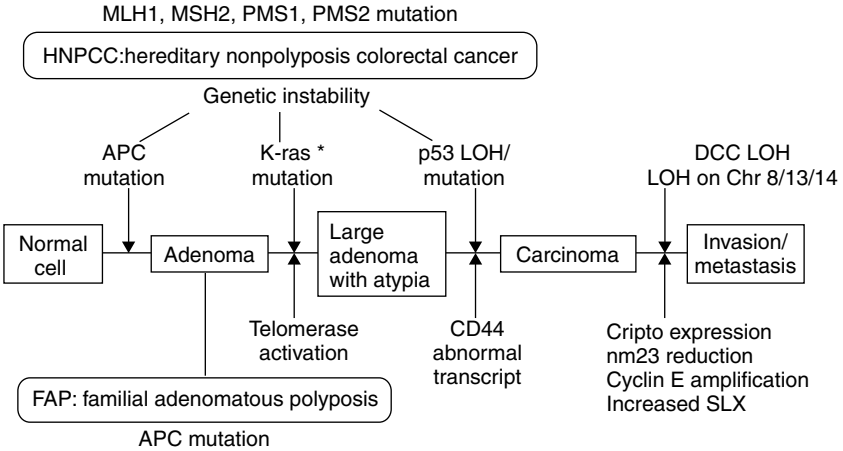

Fig. 5 A major genetic pathway for colorectal carcinogenesis. (*K-ras mutation is infrequent in flat adenoma)

genetic and epigenetic alterations responsible for colorectal carcinogenesis and abnormal growth factor/cytokine network, which is implicated in the progression and metastasis of colorectal cancer.

4.1 Genetic and Epigenetic Alterations in Colorectal Cancer

The *APC* gene, first isolated as a causative gene for familial adenomatous polyposis (FAP), encodes a large protein of 2843 amino acids, which forms a complex with α-and β-catenins and may mediate cell adhesion, cytoskeletal anchoring, and signal transduction. The *APC* gene is abnormal in the germline of FAP patients. LOH and mutations of the *APC* gene occur in 60% of sporadic colorectal adenomas and adenocarcinomas. These tumors harbor loss of the *APC* gene in one allele and mutation of the gene in the remaining allele, supporting Knudson's two-hit theory. The characteristic of the mutation is a base substitution that leads to a stop codon (nonsense mutation), which occurs in about 70% of FAP kindred. The APC alterations are found even in small adenomas with mild atypia. The tumor-suppressor function of APC has also been demonstrated in mouse models. These results and animal models show that inactivation of APC is an initiating genetic event for colorectal tumorigenesis.

The major tumor-suppression activity of APC is regulation of β-catenin. APC's association with β-catenin and promotion of the degradation of β-catenin are most relevant to its tumor-suppressor function. APC binds not only β-catenin but also glycogen synthase kinase-3β (GSK3β) and Axin. APC and Axin serve as a scaffold to facilitate the phosphorylation of β-catenin by GSK3β. The phosphorylated β-catenin is ubiquitinated by β-Trcp and the ubiquitinated β-catenin is then degraded by proteasome. Mutant APC proteins cannot regulate the degradation of β-catenin, resulting in excessive β-catenin that interacts with T-cell factor (TCF)-4 and translocates into the nucleus. The β-catenin/TCF-4 complex then activates the expression of many genes including *c-myc*, matrix metalloproteinase-7 (*MMP-7*), peroxisome proliferator-activated receptor δ (*PPARδ*) and cyclin D1, leading to promotion of colon tumorigenesis. In fact, overexpression of *c-myc, PPARδ* and cyclin D1 is observed in colorectal cancer. A recent study of PPARδ deficient (Ppard$-/-$) mice has shown that colon tumor formation is significantly greater in mice nullizygous for PPAR, suggesting that PPARδ attenuates colon carcinogenesis. It is contrary to previous reports suggesting that activation of PPARδ is causally associated with colon polyp formation. Further work is necessary to clarify the role of PPARδ in colon carcinogenesis.

On the other hand, somatic mutations of β-catenin are detected in both human and rodent colorectal tumors that do not have the APC mutation. All the β-catenin mutations found in colorectal cancers occur at the critical region for phosphorylation of β-catenin by GSK3β. The mutant β-catenin is resistant to APC-mediated degradation.

Mutation in the *K-ras* oncogene is involved in the progression from small adenoma with mild atypia to large adenoma with severe atypia. About 40 to 50% of large adenomas with severe atypia and adenocarcinomas contain K-ras point mutations at codon 12 or 13, compared to only 10% of small adenomas with mild atypia. Conversely, the frequency of K-ras mutation is lower (<10%) in superficial-type or flat adenomas even in the presence

of significant atypia. Much evidence indicates that mutation of K-ras alone can bring about a hyperplastic lesion that has a limited potential to progress to larger tumors. Mutant K-ras can, however, promote tumor progression in lesions initiated by APC mutation.

LOH of the *p53* gene locus is detected in about 80% of colorectal adenocarcinoma, and most harbor inactivation of the *p53* gene in both alleles. Because only 5 to 20% of the adenomas have p53 inactivation, it must play a crucial key in the transition from adenoma to adenocarcinoma. There are hot spots for point mutations in the highly conserved regions such as codon 175, 248, and 273, where G:C to A:T transitions occur. Abnormal accumulation of p53 protein detected by immunohistochemistry is frequently associated with deeply invasive carcinomas and carcinomas with metastasis. Almost all mutant p53 proteins derived from cancers have altered sequence-specific DNA binding and transcription activities.

Overexpression of *c-erbB2* has been reported in 80 to 100% of colorectal cancers. The amplification of *c-erbB2,* which is common in intestinal type gastric cancer, occurs in about 10% of colorectal carcinomas. Moreover, the cyclin E gene, a positive regulator of cell cycle progression, is amplified in about 10% of colorectal carcinomas. The overexpression of cyclin E is detected in 5% of adenomas and in 20% of adenocarcinomas. Among adenomas, a significant correlation is observed between cyclin E expression and the grade of atypia. Overexpression of cyclin E is prominent in carcinoma invading the submucosa or deeper compared to those limited to the mucosal layer. Cyclin E expression is thus a candidates molecular biomarker for predicting malignant progression of colorectal as well as gastric cancers. Reduction in p27 expression participates in progression and poor prognosis of colorectal cancer as well.

LOH of 18q including *DCC, Smad4,* and *Smad2* genes is frequently associated with advanced colorectal cancer. Among them, *DCC* and *Smad4* play important roles in colon cancer progression. LOH of the *DCC* gene is rare in adenoma but frequent (about 70%) in adenocarcinoma. LOH of *DCC* increases as the tumor invades deeply, and almost all the metastatic liver tumors show this LOH. Moreover, reduced expression of *DCC* in colorectal cancer is correlated with a poor prognosis. *DCC* encodes a receptor for netrin-1, but its function in normal colon epithelial cells remains unclear. *Smad4* encodes a protein that plays a critical role in the TGF-β signal transduction pathway. Although *Smad4* was isolated as a tumor-suppressor gene for pancreatic cancer, somatic mutations of *Smad4* frequently take place in advanced colon cancer, suggesting that Smad4 inactivation confers progression of colorectal cancer. In addition, *Smad4* germline mutations are responsible for juvenile polyposis, an autosomal disease that has high susceptibility for hamartomatous polyposis and gastrointestinal cancer.

In addition to these molecular events, and as mentioned for gastric cancer, telomere reduction may result in chromosomal instability and telomerase reactivation. The colorectal adenomas and adenocarcinomas share shorter telomeres than those in normal tissues. We have found that more than 90% of colorectal adenocarcinomas express extremely high levels of telomerase activity regardless of tumor staging and histological differentiation. All the adenomas also exhibit considerable levels of telomerase activity. Telomerase activity and stabilization of telomeres occur concomitantly with the acquisition of

immortality, contributing to an early stage of colorectal carcinogenesis.

Beside the major genetic pathway (adenoma–carcinoma sequence), an alternative genetic pathway exists for colorectal carcinogenesis. The so-called *de novo* carcinogenesis exhibits no adenoma–carcinoma sequence but develops directly from the colorectal epithelial cells that share p53 inactivation, followed by APC inactivation. K-ras mutation is not detected in *de novo* carcinogenesis. This type of colorectal carcinogenesis is frequently found in Japanese patients.

Tab. 4 Differences between MSI positive and MSI negative colorectal cancers.

	MSI +	***MSI −***
Location	Proximal	Distal
Ploidy	Near diploid	Aneuploid
Chromosomal instability	Rare	Common
Mutation Frequency		
P53	Low	High
APC	Low	High
TGFβ RII	High	Low
BAX	High	Low
Methylation	High	Low
Survival	Better	Worse
Hereditary syndrome	HNPCC	FAP

4.2 Factors Associated with Increased Incidence of Colorectal Cancer

Genetic and epigenetic alterations in DNA mismatch repair genes including hMHL1 and hMSH2 raise MSI that has implications for predisposition to colorectal cancer. The MSI occurs in 10 to 15% of sporadic colorectal cancer. These sporadic, mostly right-side colon cancers with MSI are associated with hypermethylation of the CpG islands in the hMLH1 promoter, resulting in loss of hMLH1, loss of function of other genes such as *p16*, defective mismatch repair, and widespread MSI. Hereditary nonpolyposis colorectal cancer (HNPCC), caused by inherited germline mutations in hMLH1 and hMLH2, accounts for 3 to 10% of colorectal cancer. Genes coding for TGFβ type II receptor, insulin-like growth factor (IGF)2 receptor, proapoptotic protein BAX, cell cycle regulator E2F-4, and mismatch repair proteins MSH3 and MSH6 are mutated in HNPCC or MSI sporadic colon cancer.

Some differences between MSI positive and MSI negative colorectal cancers are presented in Table 4. Tumor location, ploidy, mutation frequency, methylation, and survival are different between MSI positive and MSI negative tumors, although there are overlaps between the two.

In addition, sporadic colon cancer with MSI is also associated with altered expression of IGF2, namely, loss of imprinting (LOI) of IGF2. Importantly, the normal colonic mucosa exhibits aberrant hypermethylation and LOI of IGF2 as a sign of a field defect. However, Feinberg et al. have recently reported that hypomethylation of H19 and IGF2 is a mechanism for LOI and is found in both colorectal cancers and normal mucosa from the same patients. Moreover, they reported that LOI of IGF2 provides a potential heritable biomarker for colon cancer predisposition.

NF-κB activation is also associated with chronic inflammatory bowel diseases (IBD) and colorectal cancer. As mentioned in Sect. 3.2, NF-κB activation leads to production of enzymes such as iNOS and COX2 and enhanced expression of growth factors and cytokines. IBD including ulcerative colitis and Crohn's disease

induce persistent NF-κB activation in tissue macrophages and epithelial cells of the colonic mucosa. Both inflammatory bowel diseases are well known to increase the risk of colorectal cancer. The link between COX2 and colorectal cancer is supported strongly by epidemiological and experimental evidence. COX2 is overexpressed in adenomas and carcinomas of the colon. COX2-null mice are resistant to colorectal carcinogenesis. Long-term consumption of aspirin or other COX inhibitors has been reported to reduce the relative risk of colorectal cancer. These results indicate that COX2 contributes to colorectal tumorigenesis.

4.3 Abnormal Growth Factor/Cytokine Network in Colorectal Cancer

Colorectal carcinomas express multiple growth factors, such as EGF and TGFα and their receptors thus creating autocrine loops. TGFα and EGF are overexpressed in colorectal adenomas and the majority of colorectal carcinomas. Coexpression of TGFα, EGF or both, and EGFR is well correlated with high grade of malignancy and metastasis.

As described in gastric cancer, NRP-1 induced by EGF is expressed in all of colorectal cancer tissues and cell lines but not in the adjacent nonmalignant colonic mucosa. A recent study of NRP-1 in colon cancer suggests that NRP-1 may contribute to colon cancer angiogenesis and that EGF and mitogen-activated protein kinase signaling may play an important role in NRP-1 regulation in colon cancer cells.

The cripto gene was originally identified in undifferentiated human embryonal carcinoma cells and encodes a 37 amino acid region that shares structural homology with other members of the EGF family. However, cripto does not bind to the EGFR and its receptor has not been identified. Strong expression of mRNA and protein for cripto is found in 60 to 80% of colorectal cancers but not in normal colorectal mucosa. It is detected in 40% of tubular adenomas and 86% of tubulovillous adenomas, respectively. These findings suggest that cripto expression may be involved in the early stages of malignant transformation. Amphiregulin (AR) is another member of the EGF family that utilizes EGFR. About half of colorectal carcinomas as well as 60% of adenomas express AR. It has been confirmed that cripto and AR act as autocrine growth stimulators for colorectal cancer cell lines. Because AR is also expressed in normal colorectal epithelium, AR may participate in the regulation of growth of normal as well as colorectal cancer cells.

TGFβ-1 is expressed in over half of colorectal cancers. Interestingly, high levels of TGFβ-1 expression in tumor cells and elevated plasma levels of mRNA are associated with advanced Dukes' stage, suggesting that there is a correlation between TGFβ overexpression and tumor progression. Moreover, circulating TGFβ-1 may serve as a predictor of liver metastasis after resection of colorectal cancer. In addition, TGFβ produced by cancer cells stimulates angiogenesis by inducing thymidine phosphorylase, regulation of extracellular matrix adhesion molecules such as carcinoembryonic antigen (CEA), and by the enhanced secretion of gelatinase B, a matrix degrading enzyme.

VEGF and bFGF are also expressed strongly in colorectal cancer in contrast to normal colorectal epithelium and adenoma. The expression of bFGF is higher in Dukes stage D than in Dukes stage B colorectal cancer. Moreover, bFGF and

VEGR are elevated in the serum of patients with aggressive advanced colorectal cancer. These circulating growth factors as well as TGFβ may be useful biomarkers for understanding angiogenesis and malignancy. On the other hand, the expression of VEGF-C and VEGF-D correlates with lymph-node metastasis in colorectal carcinoma, and these expressions are heterogeneous and elevated at the invasive edge of tumors.

Activation of the pp60src protein kinase activity occurs during colorectal tumorigenesis. The kinase activity of pp60src is highly regulated and is induced by many growth factors. Recently, pp60src has been reported to be essential for the induction of VEGF by hypoxia. The specific activity of pp60src is higher in colorectal polyp than in normal mucosa, and is further increased in colorectal carcinoma and in metastatic colon tumor in liver. Further study is needed to clarify the mechanism for increased pp60src activity during colorectal carcinogenesis.

The abnormal transcripts of the *CD44* gene are also expressed in all of colorectal cancers. As mentioned in gastric cancer, the *CD44* gene consists of at least 20 exons, of which 10 are alternatively spliced to make up variants. Among several *CD44* variants, aberrant transcripts with retention of intron 9 are best for distinguishing carcinoma tissues from normal tissues in the colorectum. However, the variants do not correlate with nodal or distant metastasis.

A candidate suppressor gene of tumor metastasis, *nm23*, encodes nucleotide diphosphate kinase and c-myc transcription factor (PuF). Although most of colorectal cancers express nm23 at higher levels than the corresponding normal mucosa, an inverse correlation is observed between nm23 expression and tumor staging. Moreover, reduced expression of nm23 is associated with distant metastasis.

Another candidate for a molecular marker that indicates metastatic potential is cell surface carbohydrate, sialyl-dimeric Le antigens. Both sialyl Lex (SLX) and sialyl Lea (SLA or Ca 19-9) as ligands bind to E-selectin, also known as ELAM-1, one of the adhesion molecules on activated endothelial cells. SLX and SLA may participate in distant metastasis through interaction between cancer cells and endothelial cells. The expression of SLX in colorectal carcinomas shows significant correlation with liver metastasis and poor prognosis.

5 Conclusion

A large number of molecular events are involved in the development and progression of gastrointestinal carcinomas. Among them, common and distinct events of genetic and epigenetic alterations are observed in esophageal, gastric, and colorectal cancers. MSI confers the initial step of gastric and colorectal carcinomas, while it is less involved in esophageal SCC. Chromosomal instability (telomere reduction) and telomerase activation participate commonly in the very early stage of gastrointestinal carcinogenesis. p53 inactivation and RUNX3 loss by promoter hypermethylation are also common events, although RUNX3 loss is less in colorectal cancer. APC LOH and DCC LOH are commonly detected in the majority of the three gastrointestinal cancers, although APC mutations occur mainly in colorectal cancer. K-ras mutation is often found in colorectal cancer, whereas it is extremely rare in esophageal SCC and gastric cancer. Amplification of the cyclin D1 gene

is preferentially found in esophageal SCC, while the gene amplification of cycline E is frequently associated with both gastric and colorectal adenocarcinomas. Reduced expression of the CDK inhibitors such as p16 and p27 is often found in gastrointestinal cancers. In gastric cancer, the pattern of genetic and epigenetic alterations also differs depending on the two histological types, intestinal or well-differentiated type and diffuse or poorly differentiated type. The amplification of *c-met* and *K-sam* genes and the mutation/loss of the E-cadherin gene as well as *RARβ2* loss occur preferentially in diffuse type, whereas the amplification of *c-erbB2* gene, pS2 reduction, p16 loss and hMLH1 loss as well as APC mutation is predominantly found in intestinal type.

In addition to these events, gastrointestinal cancer cells express a broad spectrum of the growth factor/cytokine receptor systems that organize complex interactions between cancer cells and stromal cells, which confer cell growth, apoptosis, morphogenesis, angiogenesis, progression and metastasis. However, these abnormal growth factor/cytokine networks are also evidently different among esophageal, gastric, and colorectal cancers, respectively. Importantly, NF-κB activation induced by inflammation may act as a key player for induction of growth factor/cytokine networks in gastrointestinal cancers.

Overall, the observations on the molecular events involving growth factors and oncogenes in gastrointestinal cancers will no doubt provide a deeper understanding of prevention, molecular diagnosis, and therapeutics of these cancers. In fact, by applying these molecular events of gastrointestinal cancers to routine clinical practice, we have implemented molecular pathological diagnosis of gastrointestinal cancer in collaboration with Hiroshima City Medical Clinical Laboratory since 1993. We have analyzed more than 10 000 cases of gastrointestinal biopsy and surgery and then obtained additional information on differential diagnosis, biological malignancy, and tumor multiplicity. We believe this approach will better serve science, but more importantly, patient care.

Keywords

Angiogenesis
The production of blood vessels.

Apoptosis
Programmed cell death resulting from genetic damage and/or absence of growth regulators.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Edited by Robert A. Meyers.
Copyright © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim.
ISBN: 3-527-30547-5

Autocrine
Describing the actions of a growth factor/cytokine on the same cell that produces the growth factor.

Cancer
The cell mass that results from the uncontrolled production of genetically altered cells in an animal.

Cell Production
The process of hierarchical proliferation and maturation of tissue-specific stem cells, which leads to the generation of mature cells in a specific tissue.

Chemokines
Structurally related smaller cytokines (8–10 kDa) that act on inflammatory cells.

Colony stimulating Factors
Proteins that stimulate the proliferation and maturation of myeloid precursor cells.

Cytokines
Proteins released from one cell that modulate the proliferation, differentiation, and/or function of cells in a specific lineage.

Differentiation
The alteration in gene expression as precursor cells divide and progress toward their functional forms.

Endocrine
Describing the effects of a growth factor/cytokine/hormone produced in one organ on the cells of another organ.

Growth Factors
Proteins that influence the proliferation and maturation of tissue-specific precursor cells.

Hormones
Molecular signals released from one cell that modulate the function or production of other cells. In the broadest sense, the term *hormone* includes steroids, peptides, and lipids. In traditional physiology, the term was used to describe the molecules released by one organ that acted on the cells of another organ.

Interleukins
Proteins released from stromal or hematopoietic cells that influence the proliferation, self-renewal, commitment, and/or maturation of hematopoietic cells.

Lymphangiogenesis
The production of lymphatic vessels.

Lymphokines
Proteins that modulate the proliferation, maturation, or function of lymphoid cells.

Paracrine
Describing the actions of a growth factor/cytokine on cells in close vicinity to the cells producing the growth factor.

Receptors
Cell surface proteins that are stimulated by exogenous ligands (e.g. growth factors) to transfer a signal to the cytoplasmic compartment of a cell.

Signal Transduction
Transfer of extracellular (membrane) interactions to intracellular (cytoplasmic and/or nuclear) responses such as enzyme activation and/or modulation of gene transcription.

Stem Cells
The cells responsible for the renewal of cells in specific lineages. Stem cells have the capability of dividing to renew themselves or dividing to produce differentiated progeny that are committed to the production of mature cells.

Cell production in all tissues of multicellular organisms is under the control of a network of tissue-specific protein regulators called *growth factors*. Although the growth factor network may be modulated by circulating hormones, these regulators are usually produced in the tissue in which they function. Growth factors have been identified in the epithelial, neural, lymphoid, myeloid, and hepatic systems; in many cases, a number of closely related growth factors are produced in each tissue. As well as controlling the normal production of mature cells, growth factors are important for regulating inflammatory, wound-healing, and antiviral responses. Many diseases appear to be associated with inappropriate growth factor production or responses. Overproduction of growth factors can lead to accumulation of cellular deposits and infiltration of tissues by inflammatory cells. Although cancers arise as the result of numerous genetic lesions, many metastatic cancers appear to be driven by the autocrine action of growth factors or mutations, which lead to activation of the receptor.

New therapeutic approaches to cancer involve the use of specific growth factors to improve hematopoietic recovery from cytotoxic or radiation therapy. Furthermore, growth factor antagonists and growth factor receptor inhibitors are being developed to suppress the proliferation and metastasis of the tumor cells. An understanding of the mechanism of action of growth factors and the range of action of these proteins is also important for developing effective therapies for autoimmune diseases, such as, rheumatoid arthritis, skin diseases, and diabetes.

1 Introduction

Multicellular organisms must control the production, maturation, and function of cells in each tissue or organ. It is now clear that locally secreted proteins modulate the cell physiology of each tissue. These regulatory proteins have been given a variety of names, including growth factors, cytokines, and interleukins (ILs). It is well known that the endocrine systems consist of a network of circulating regulatory molecules (hormones) that includes proteins, peptides, and steroids; growth factors can be considered to be an extension of the endocrine system. While there is a direct overlap between the growth factor and endocrine systems, it is often helpful to consider that the major actions of endocrine hormones occur in tissues remote from their tissue of origin, whereas growth factors appear to have a major function within the tissues that produce them.

In the main, there is no functional or structural characteristic that distinguishes different classes of growth factors – most appear to be capable of stimulating multiple biological responses that depend critically on the differentiation state of their target cells. For example, one of the hematopoietic growth factors, granulocyte colony stimulating factor (G-CSF), stimulates the proliferation of immature bone marrow cells as well as activating bacterial killing by mature neutrophils. For most growth factors, so many distinct biological effects have been observed *in vitro* that it is not yet possible to define their specific role in particular tissue systems. However, both pharmacological and genetic studies have demonstrated that growth factors can alter cell production, organogenesis, and disease susceptibility in animals. It should be noted that the action of a particular growth factor will usually depend on the presence of other growth factors, the availability of target cells, and the display of the appropriate cell surface receptors (Fig. 1).

Growth factors stimulate cells by binding to specific cell surface proteins called *receptors*. Upon binding the growth factor, many receptors dimerize and activate intracellular kinase networks. Some receptors, such as the epidermal growth factor receptor (EGFR), are ligand-dependent tyrosine kinases; others, such as the IL-2 receptor, associate with and activate particular membrane-associated tyrosine kinases. Activation of these enzyme systems can have effects on cell metabolism, membrane turnover, cytoskeletal organization, cell movement, and cell division.

Cell production occurs continuously throughout embryonic and adult life. During the earliest stages of development, cytokines such as leukemia inhibitory factor (LIF) appear to be necessary to facilitate implantation, to stimulate cell division, and to prevent differentiation (i.e. to maintain pluripotentiality). At the later stages of blastogenesis and gastrulation, cells display a bewildering array of growth factor/cytokine receptors, and the availability of particular ligands can then determine the motility, connectivity, and proliferative state of the cells. Often organs are remodeled through the absence of a tissue-specific growth factor. Late in gestation, the vitreous humor of the eye is full of hyalocytes – macrophage-like cells that depend on granulocyte/macrophage colony stimulating factor (GM-CSF) for their survival (and perhaps function). Normally, these hyalocytes persist until a few days after birth, when GM-CSF levels decrease and hyalocytes undergo rapid, apoptotic death. In mice engineered to overexpress GM-CSF, the hyalocytes persist in the vitreous humor.

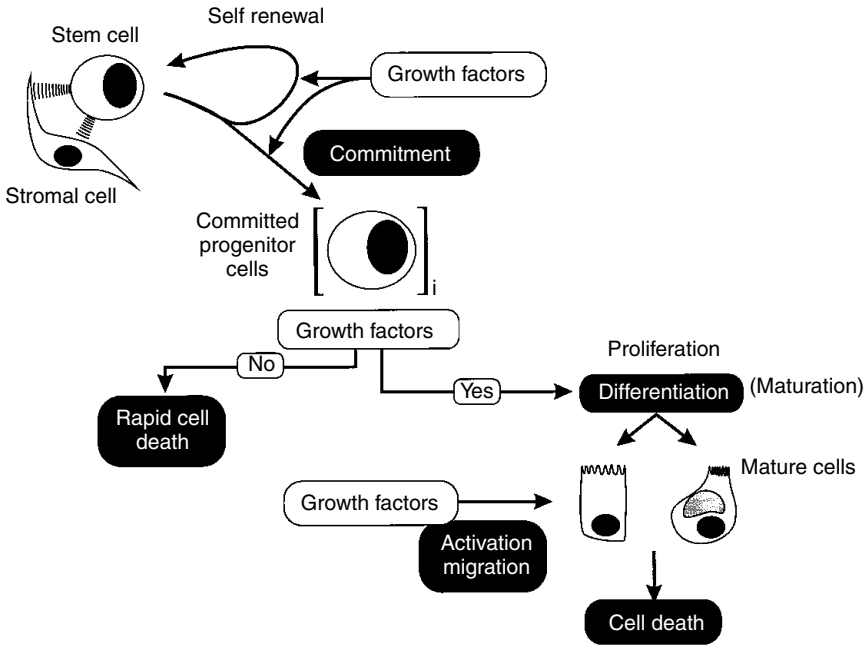

Fig. 1 There are several sites of action of growth factors during the production of cells. The action of the growth factor is likely to be quite different at the different stages of maturation.

The trafficking of mature cells between organs, and in particular from the blood into tissue spaces and even the mucosal layers, appears to be controlled by growth factors/cytokines and/or chemokines. The presence of several cytokines and membrane proteins from foreign organisms can trigger a strong proliferative response or the activation of effector functions. The action of bacterial cell wall proteins and lipids synergizes with regulators such as G-CSF or GM-CSF to induce intense antibacterial responses.

Recently, our traditional concepts of growth factor physiology have been challenged by the existence of genetically deficient animals. Often, the physiological actions of specific growth factors have been inferred from the properties of these molecules *in vitro*. For example, G-CSF stimulates the production of neutrophils in bone marrow cultures. Mice have been produced that have a genetic disruption of the G-CSF locus. Despite a profound neutrophil deficiency, these mice still produce some neutrophils. Thus, G-CSF cannot be the only growth factor controlling neutrophil production. Similarly, mice that lack the ability to produce transforming growth factor (TGF-α) have normal skin, esophagus, stomach, and colon mucosas. Although there are several growth factors closely related to TGF-α, it is not clear whether mucosal cell production continues because of the availability of other growth factors or whether the actual function of TGF is quite different from our current hypotheses.

It is not only the growth factors/cytokines that occur as families but there are also families of receptors for specific growth factor families. There are at least

four members of the EGFR family: *EGFR*, *erb B2 (HER 2)*, *erb B3 (HER 3)*, and *erb B4*. These receptors form both homodimer and heterodimer signaling complexes, all of which are capable of stimulating specific sets of intracellular signaling pathways.

Although there is a vast array of growth factors and cytokines, the receptor systems are built up from sets of domain structures. Thus, the hematopoietin receptor families have homologous hematopoietin, fibronectin, and immunoglobulin domains, which form the extracellular binding site. The ligand-binding domains are usually attached to a short intracellular tail. The nerve growth factor (NGF)/tumor necrosis factor receptor family consists of four to eight ''six-cysteine'' domains in the extracellular region, and these are attached to intracellular domains associated with apoptosis or CD-40-like domains. The other major class of receptors encodes ligand-activated intracellular tyrosine kinases. Again, the extracellular regions have immunoglobulin and fibronectin-like clusters, which are attached to the intracellular kinase.

Receptor activation appears to require ligand-induced aggregation, which triggers either the receptor kinase or associated intracellular kinases. Once activated, the receptor enzymes stimulate several intracellular signaling cascades. While the relative importance of the different signaling cascades has not been determined in detail, it appears that many tyrosine kinase receptors activate the *rasraf-map* kinase pathways, and many of the cytokine (hematopoietin) receptors activate the *JAK/STAT* signaling system. These signaling pathways are dependent on continuous occupancy of the receptor by ligand and even then, receptor downmodulation and phosphatase activation tend to dampen the signaling processes.

Clearly, the normal growth and differentiation of cells are controlled by the growth factor/cytokine network. However, the complex events triggered by the cytokine network are also the major targets for tumorigenic lesions (e.g. autocrine growth factor production, constitutively activated receptors, or intracellular signaling proteins forced into the active state by mutation(s)). If two or more of these lesions occur in cells that have damaged tumor suppressor genes, there is a considerable likelihood that the cell will proliferate and differentiate uncontrollably – that is, become cancerous.

2 Discovery

The incredible potency and diverse biological activities of growth factors have led to multiple, independent discoveries. A typical example is the identification of interferon 2 as a member of a family of proteins capable of inducing antiviral responses and its discovery as a growth factor in the lymphoid system, where it was called *interleukin-6* (IL-6). Some growth factors, such as fibroblast growth factor (FGF), have been identified independently in as many as 20 different biological systems. While these studies emphasize the multiple actions of growth factors, some confusion has developed with regard to their nomenclature and their likely physiological function(s). It should not be assumed that a particular action of a growth factor *in vitro* is automatically related to its role in the whole animal.

The first growth factor identified in 1906 was erythropoietin (epo). This discovery arose from physiological observations on the humoral control of production of red blood cells. While NGF and epidermal

growth factor (EGF) were discovered in the early 1950s, as a result of observations on the innervation of transplanted tumors, the discovery of most other growth factors has been due to their activity in laboratory culture systems. More recently, growth factors such as stem cell factor (also called the c-*kit* ligand) and thrombopoietin have been identified as a consequence of the characterization of their respective cell surface receptors. Table 1 lists the chromosomal locations of many growth factors for mice and humans.

The discovery of growth factors is, in many ways, a reflection of the serendipity and excitement of science. Time and again they turned up in the most unexpected way. When Stanley Cohen was analyzing the nature of the molecule responsible for nerve innovation of tumors, he planned some simple experiments to test whether it was a protein, a lipid, or a nucleic acid. One of these tests required the use of a phosphodiesterase (a hydrolytic enzyme, extracted from snake venom, which breaks down nucleic acids). Instead of destroying the growth factor, the enzyme appeared to increase its activity: in fact, the enzyme preparation was contaminated with nerve growth factor. Cohen recognized the connection between snake venom and the mouse salivary gland – a unique tissue that contains almost 1 mg g^{-1} wet weight of both NGF and EGF. Eventually, both NGF and EGF were isolated from the mouse salivary gland. Curiously, only the male mouse salivary glands have this enormous store of growth factors, and to this day it is not clear why they are there.

The human equivalent of EGF was first recognized by an activity (urogastrone) in urine, which inhibited gastric acid secretion (and acid-induced ulceration) when injected into dogs. Harold Gregory designed the purification procedure for urogastrone and after many years obtained sufficient quantities to determine its amino acid sequence. This substance was homologous to the mouse salivary gland EGF and consequently, urogastrone was renamed as *human EGF*.

The growth factors/cytokines that control the production of white blood cells were discovered at the same time, but independently, by scientists in Australia and Israel. It was several years before these groups realized they were working on the same set of molecules. The two Australians, Ray Bradley and Donald Metcalf, had been trying to grow leukemic cells; the two Israelis, Dov Pluznik and Leo Sachs, thought that they had grown tissue mast cells in the laboratory. When Bradley finally ''succeeded'' in devising a method to use normal cells to stimulate the growth of small colonies of leukemic cells, he rushed the cultures over to Metcalf, who realized that some of the normal cells were in fact producing the colonies. The leukemic cells were producing a ''colony stimulating factor'' (CSF) that allowed the proliferation and differentiation of blood cell precursors to form thousands of mature neutrophils and macrophages. Pluznik and Sachs also realized that their colonies were made up of mature white blood cells.

At first, only one CSF was recognized, but it gradually became clear that there were several distinct CSFs: macrophage CSF (called CSF-1 or M-CSF), granulocyte/macrophage (GM)-CSF, granulocyte (G)CSF, and even a molecule that stimulates cell production in almost all of the hematopoietic lineages (initially named *multi-CSF*, now known as *interleukin 3* (*IL-3*)). These CSFs were initially recognized by their activities in laboratory culture systems; indeed, many scientists believed the CSFs were artifacts and were simply

Epo receptor	19pter-q12	9
Leukemia inhibitory factor	22q12.1–12.2	11A1–A2

nutrients missing from imperfect tissue culture media. Although our knowledge of the physiology of the CSFs is still rudimentary, genetic studies and clinical trials have shown how powerful these regulators are *in vivo*. Many cancer patients are now treated with G-CSF or GM-CSF to improve the rate of hematopoietic recovery after cytotoxic chemotherapy.

3
Growth Factor Families (see Figure 2)

3.1
Insulin-like Growth Factors

In 1922, Banting and Best discovered insulin, the regulator of glucose metabolism, in pancreatic extracts. Insulin was the first protein to have its amino acid sequence determined. It is now known that insulin is synthesized as a single precursor protein, which is processed and secreted as a disulfide-linked heterodimer. As well as controlling blood glucose levels, insulin stimulates cell proliferation; however, two other closely related proteins, insulin-like growth factors I and II (IGF-1 and IGF-II), are more potent stimulators of cell proliferation. IGF-I was discovered as the protein in plasma responsible for non-suppressible insulin-like activity. IGF-I, which was known for some time as a somatomedin, also mediates the action of growth hormone. IGF-II was the first growth factor to be associated with the aberrant growth of tumor cells in the laboratory. While the members of this family circulate in the serum, their availability is controlled by specific binding proteins (BPs). The cell surface receptors for insulin

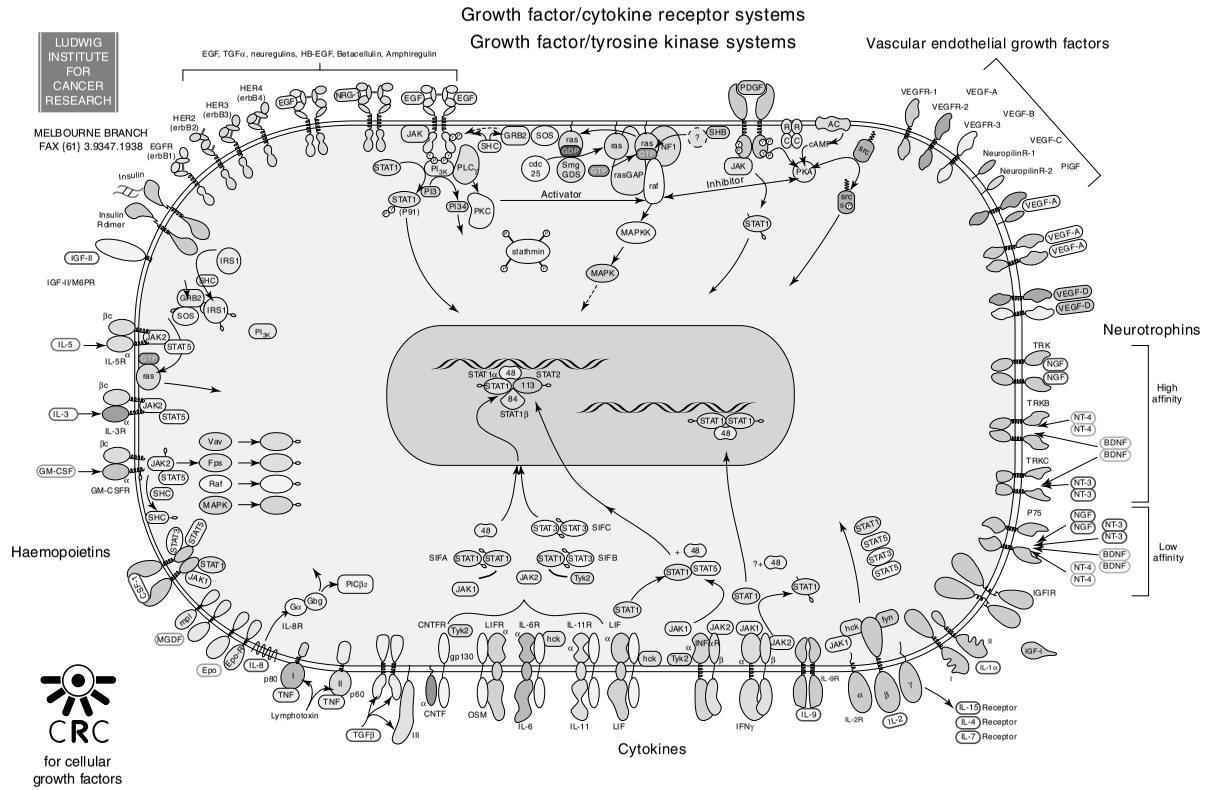

Fig. 2 Growth factors/cytokines and their receptor signaling systems.

and IGF-I are composed of four chains ($\alpha 2$, $\beta 2$). The β-chains are transmembrane, ligand-dependent tyrosine kinases, and the α-chains bind the ligand. The IGF-II receptor is a large (2000 amino acids) single-chain structure with no obvious intracellular catalytic domain. The IGF-II receptor also functions as the receptor for mannose-6-phosphate, which targets acid hydrolases to liposomes. It has been suggested that these two binding specificities might regulate complementary processes during tissue remodeling.

The actions of the IGFs are modulated by a complex set of circulating and tissue-specific binding proteins. The IGFs circulate in a complex with IGFBP-3 (this prevents degradation and excretion). Upon release from the IGFBP-3 complex, the IGFs complex with two other IGFBPs to be transported into the tissue compartments. Again, the BPs appear to control the release and action of the IGFs in their target tissues. This complex set of interactions ensures that the effective concentrations of free IGFs are kept under control and maintained for longer times than many other growth factors.

3.2 Nerve Growth Factors/Neurotrophins

Nerve growth factor, a humoral substance produced by some tumors, is responsible for innervation of these tumors. The discovery of NGF in the 1940s initiated the search for other tissue-specific growth factors and led quickly to the identification of EGF (see Sect. 3.3). Initially NGF was isolated from the salivary glands of male mice as a complex of three proteins; however, the active component is a single protein of molecular weight 30 000. The three-dimensional structure of NGF has revealed a separate, novel arrangement of three extended segments of twisted antiparallel β-sheet. Several other neurotrophins [brain-derived neurotrophic factor (BDNF), NT-3, and NT-4/5] have been discovered. BDNF stimulates peripheral sensory ganglia as well as cholinergic and dopaminergic neurons. More recently, there have been reports of a glial growth factor that is a differentially spliced form of a ligand for the *erb B3* or *erb B4* receptors.

Detailed structure–function studies have identified many of the residues required for the binding of NGF and BDNF to the low affinity (1–5 nM) neurotrophin receptor p75. However, the role of this receptor in NGF signaling is still unclear. The other class of neurotrophin receptors, *trk A, trk B,* and *trk C,* are ligand-activated tyrosine kinases. *trk A* binds NGF, *trk B* binds BDNF or NT-4, and *trk C* recognizes NT-3.

During embryological development, the neurotrophins regulate the survival of specific classes of neurones. NGF appears to function on peripheral neurones of the sympathetic system, whereas BDNF has an effect on neural crest cells and NT-3 acts on oligodendrocyte precursors.

3.3 Epidermal Growth Factor Family

It is now 40 years since Stanley Cohen described the discovery of the factor that induces in mice both premature opening of eyelids and tooth eruption. A small protein (53 amino acids) with three disulfide bonds and two distinct folding domains, EGF stimulates lung maturation and the formation of gastrointestinal mucosa, and inhibits the secretion of acid from the gastric mucosa. EGF binds to and stimulates a single-chain tyrosine kinase receptor.

There are several growth factors related to EGF – namely, TGF-α, amphiregulin, cripto, heparin binding-EGF (HBEGF), heregulin, and β-cellulin. TGF-α was discovered as an autocrine growth factor induced by some tumor viruses. EGF and TGF-α are expressed as precursor molecules. The TGF-α precursor is expressed on the surface of cells, and the mature protein is released by specific proteolysis. Amphiregulin and the neuregulins bind to distinct receptors within the EGF receptor family.

There are four closely related tyrosine kinase receptors in the EGFR family: *EGFR, HER 2, HER 3,* and *HER 4*. The sequence homology in the ligand-binding domain is between 40 and 50%, and in the kinase domain up to 80% similarity. However, it is clear that the ligand-binding specificity for each receptor is distinct, with the *EGFR* having a preference for EGF and TGF-α, whereas *HER 3* and *HER 4* bind to the neuregulins. There is now considerable evidence that heterodimers between *EGFR* and *HER 2, HER 2* and *HER 3,* and so on, bind appropriate ligands with high affinity and activate distinct signaling pathways.

Activation of the *EGFR* kinase involves ligand-induced conformational change and oligomerization. It is still not clear how many proteins are required to form the mitogenic signaling complex, but the receptor becomes autophosphorylated as well as adding phosphate to an adaptor protein called *SHC*. Phosphorylated SHC appears to influence the subcellular location of a complex between grb2 and SOS, the exchange protein that adds GTP to *ras*. Formation of the GTP–*ras* complex initiates a signaling cascade required for mitogenic responses to EGF. While the *ras*-activated pathway may be needed for mitogenesis, *EGFR* kinase must also activate other essential pathways for mitogenesis to occur.

The inappropriate expression of the *EGFR* and *HER 2* has been associated with several tumors including gliomas, where all high grade tumors overexpress the *EGFR*. *HER 2* and *HER 3* are expressed in many breast and pancreatic tumors. It also appears that β-cellulin, *HER 3,* and activated *ras* are in part responsible for many pancreatic carcinomas. By blocking autocrine growth factor production or the *EGFR,* it is possible to sensitize colonic tumors to chemotherapeutic drugs such as *cis*-platinum. The EGF receptor family are appropriate targets for anticancer signaling therapeutics.

3.4 Transforming Growth Factor (TGF-β) Family

TGF-β is released after tumor virus infection of fibroblasts. Indeed, TGF-β synergizes with TGF-β to induce large colony formation by normal rat kidney (NRK) cells. TGF-β was also isolated independently because of its ability to inhibit the proliferation of epithelial cells. TGF-β also inhibits the proliferation of both hematopoietic and lymphoid cells. TGF-β induces the differentiation of bronchial epithelial cells and prechondrocytes, but inhibits the differentiation of adipocytes and myocytes. A latent form of TGF-β is released from platelets as a complex with a specific binding protein. Active TGF-β can be released from the complex either by proteolysis or by acid treatment. Several other cytokines belong to the TGF-β superfamily: two forms of TGF-β have been isolated from platelets and three other related sequences have been detected by screening cDNA libraries. Inhibin, the Müllerian

inhibitory substances (MIS), the bone morphogenic proteins (BMPs), and activin are all related to TGF-β. The availability of the three-dimensional structure for TGF-β will allow models to be developed for the other family members.

TGF-β induces the synthesis of extracellular matrix (ECM) components *in vivo* and *in vitro*. TGF-β is also a powerful enhancer of monocyte function and a suppressor of lymphopoiesis. Mice that lack a functional *TGF-β1* gene have been produced; while they are born as apparently normal animals, within two weeks they develop severe autoimmune and hematopoietic defects.

TGF-β appears to control the production and action of ECM proteins by regulating secretion, increasing the level of integrin receptors, and decreasing the breakdown of ECM proteins. Taken together, these actions appear to have the capacity to control organogenesis during embryological development. In adults, TGF-β acts as a profound immunosuppressant. Indeed, some patients with brain tumors secrete so much TGF-β that their immune systems fail to function effectively. TGF-β may enhance the granulation phase of wound-healing, but the presence is presumably timed carefully, inasmuch as excess levels inhibit epithelialization. Interestingly, both TGF-α and TGF-β are produced by many tumors. It has been postulated that the tumors often downregulate the TGF-β receptors and are not responsive to the inhibitory actions of this growth factor, while the action of the TGF-β on surrounding cells leads to the secretion of extra ECM and thus, to a more favorable environment for tumor proliferation.

Three receptors have been identified for TGF-β: types I, II, and III. Types I and II bind TGF-β with high affinity (K_D5–25 pM). The type III TGF-β receptor is a large transmembrane proteoglycan with no obvious cytoplasmic signaling motif. The TGF-β type II receptor has ligand-dependent Ser/Thr kinase activity, which appears to signal growth inhibition. The type II receptor requires the type I receptor for ligand binding.

3.5 Platelet-derived Growth Factors (PDGFs) and Vascular Endothelial Growth Factors (VEGFs)

For more than 70 years it has been known that serum, but not plasma, stimulates cells to proliferate in culture. Not until the early 1970s, however, was it discovered that the growth factors in serum are actually released from platelets. It took almost 10 years of protein chemistry to purify and sequence the first platelet-derived growth factor (PDGF) – a disulfide-linked heterodimer of two related polypeptides (A and B), each containing approximately 100 amino acids. At the same time as the amino acid sequence for PDGF was determined, the nucleotide sequence for the oncogene (v-*sis*) encoded by the simian sarcoma virus was characterized. The protein sequence predicted from the v-*sis* gene is closely related to the PDGF-β chain.

Different cell types are known to secrete either PDGF-AA or PDGF-BB homodimers, both of which act as growth factors for fibroblasts, smooth muscle cells, and glial cells. There appear to be two forms of the PDGF receptor monomer (α and β), and these can combine to produce several, functional receptor dimers: $\alpha\alpha$, $\alpha\beta$, and $\beta\beta$. Whereas the $\alpha\alpha$ receptor responds to all forms of PDGF (i.e. AA, AB, and BB) the $\beta\beta$ receptor responds only to PDGF-BB. The PDGF receptors are typical ligand-dependent tyrosine kinases, but the cytoplasmic domain contains an

insert that modulates the intracellular signaling processes. PDGF increases the rate of wound-healing in rodents, and initial reports indicate that it may be a valuable agent for treating cutaneous ulcers in diabetic patients.

Both the PDGF-A and PDGF-B chains are synthesized in a wide variety of cells – endothelium, muscle, and macrophages. The A-chain is induced by fibroblasts in response to other growth stimuli – that is, a normal autocrine loop appears to control the proliferation of some cell types. This autocrine function can be disturbed in several diseases, such as sarcomas, atherosclerosis, and rheumatoid arthritis.

Although the PDGF family is small, there is a related set of growth factors – the vascular endothelial growth factor (VEGF) family that controls the production of endothelial cells. Several isoforms of VEGF are produced from a single gene by differential splicing of its mRNA precursor. The smallest form, $VEGF_{121}$, is a weak acidic protein that does not bind to heparin and is secreted from cells in a freely diffusible form. The longer forms of VEGF bind to heparin and appear to be released in response to plasmin.

VEGF stimulates the production of endothelial cells from both small and large blood vessels. As well as promoting angiogenesis, VEGF stimulates monocyte chemotaxis. VEGF is produced by many neoplastic cells. Interestingly, antibodies against VEGF can inhibit the production of blood vessels *in vivo*, and as a consequence, inhibit the growth of human tumor cell lines. Similarly, negative dominant VEGF receptors can inhibit the vascularization of experimental tumors.

Actually, there are four closely related growth factors in the VEGF family: VEGF, VEGF-B, VEGF-C, and VEGF-D. The first two family members stimulate the formation of blood vessels, whereas VEGF-C and VEGF-D stimulate the production of the lymphatic vessels.

3.6 Fibroblast Growth Factors (FGFs)

In the 1930s, it was discovered that brain and pituitary extracts stimulate the proliferation of fibroblasts in culture. By the mid-1980s, two forms of FGFs had been identified, purified, and sequenced. Both the acidic (a-FGF) and basic (b-FGF) forms are single-chain proteins of approximately 140 amino acids, and 55% of their amino acid sequences are identical. There are several other members of the FGF family: *wnt*-2, *hst/k*53, *FGF*-5, *FGF*-6, *FGF*-7 (keratinocyte growth factor, KGF), *FGF*-8, and *FGF*-9 (glial activating factor), and there appears to be a distant homology (20–25%) to ILs 1α and β. Both a- and b- FGFs stimulate the proliferation of cells, including colonic and breast epithelia, endothelial cells, and muscle cells. Although a-FGF and b-FGF are associated with the ECM, neither protein has a classical signal peptide that would direct their secretion. It is still not known how these proteins are released from cells.

Although a-FGF and b-FGF bind to the same set of cell surface receptors, b-FGF has the higher affinity for its receptor. While the high affinity of the FGFs for heparin-sulfate is useful for their purification, this property often interferes with binding studies to the cell surface. FGFs are potent angiogenic agents and are also capable of accelerating the healing of cutaneous wounds and damaged nerves. b-FGF is mitogenic for oligodendrocytes, astrocytes, and Schwann cells, and it acts to prolong the survival of neuronal cells in culture. In pharmacological doses, b-FGF

can enhance the remyelination of neuronal sheaths and can prevent the death of neurons in the dorsal root ganglion.

FGFs have also been purported to play a role in tumor blood vessel formation. A retrovirus encoding *FGF-4* (also called K-FGF) induces tumors in mice. Furthermore, the *FGF-4* gene is amplified in a number of breast cancers. *FGF-7* (KGF) and its receptor (*FGFR-2*) are both expressed in prostate cancer cells. A variant of *FGFR-2* (K-sam) has also been detected in stomach cancer cells and appears to be associated with the tumor phenotype.

3.7 Hepatocyte Growth Factor (HGF)

Originally discovered as a factor that increases the motility and spreading of cells (called *scatter factor*), hepatocyte growth factor (HGF) stimulates the proliferation of primary hepatocytes and increases the invasiveness of endothelial and epithelial cells. HGF appears to be involved in liver regeneration, tumor progression, and several embryological processes. HGF is a 92-kDa disulfide-linked heterodimer consisting of a light chain (33 kDa) and a heavy chain (62 kDa), which are produced from a single-chain precursor.

The HGF receptor (c-*met*) is a 190-kDa heterodimer in which the α-chain (50 kDa) appears to be extracellular and is linked to the β-chain (145 kDa), which is a membrane-spanning protein with a cytoplasmic tyrosine kinase domain, via a disulfide bond. It is expressed in a number of epithelial tissues, including liver and colon. Interestingly, a fragment of HGF containing two Kringle domains binds to c-*met* and stimulates the motility response and the receptor tyrosine kinase activity, but does not stimulate a mitogenic response in primary rat hepatocytes. Mutations in c-*met* have been associated with a number of cancer types. There are two other receptors related to c-*met*: c-*ron* and c-*sea*.

3.8 Hematopoietic Growth Factors

At least 20 cytokines or growth factors have been identified by their action on the production or function of blood cells. The major classes of hematopoietic regulators are ILs, lymphokines, CSFs, erythropoietin, and stem cell factor (SCF). Table 2 lists some of the biological actions of these molecules; however, it must be emphasized that as with the other growth factors, each one has multiple activities, which are not necessarily limited to the hematopoietic system. Several hematopoietic growth factors are being used clinically: in particular, IL-2 in conjunction with lymphokine activated killer LAK cells for cancer therapy; granulocyte/macrophage CSF and G-CSF to accelerate neutrophil recovery after chemotherapy or bone marrow transplantation; epo to stimulate red blood cell production in kidney dialysis or cancer patients; and thrombopoietin (tpo) to improve the rate of platelet recovery in thrombocytopenic patients. Three-dimensional structures have been determined for a number of hematopoietic growth factors – many consist of four helical bundles packed to form a central cylinder (Fig. 3). The structure–function relationships of this class of growth factors are being examined in detail, and already several potent antagonists (e.g. for IL-1 and IL-4) have been produced. As might be expected from such a large number of hematopoietic growth factors, several classes of cell surface receptors have been identified: tyrosine kinase (e.g.

Tab. 2 Biological actions of the hematopoietic growth factors.

Name	*Action*
IL−1α/β	Stimulates thymocyte proliferation Increases expression of IL-2 receptor on T-lymphocytes
IL-2	Stimulates proliferation of T-lymphocytes
IL-3 (also called multi-CSF)	Stimulates production of cells in all myeloid lineages
IL-4	Stimulates proliferation of B-lymphocytes Stimulates production of IgM and potentiates mast cell proliferation in response to IL-3
IL-5	Induces B-cell proliferation and differentiation in the mouse only Stimulates production and activation of eosinophils
IL-6 (also called interferon β2)	Stimulates hematopoietic progenitor cells, B-lymphoid, and myeloma cells; induces acute phase responses
IL-7	Stimulates proliferation of thymocytes, T-lymphocytes (including cytotoxic T-cells), and early B-cell precursors
IL-8	Stimulates neutrophil chemotaxis and activates bacterial killing Inhibits IgE production by B-lymphocytes
IL-9	Stimulates proliferation of T-lymphoid cell lines Potentiates proliferative effect of IL-2 on fetal thymocytes
IL-10	Inhibits cytokine production by T-lymphocytes
IL-11	Stimulates production of IgG generating B-cells Induces acute phase response Augments ability of IL-3 to stimulate megakaryocyte colonies
IL-12	Stimulates cytokine production by NK cells and T-cells
IL-13	Inhibits cytokine production by monocytes and is a costimulator of B-cell lymphocyte proliferation
IL-14	Induces proliferation of activated B-lymphocytes
IL-15	Stimulates the proliferation of cytotoxic T-lymphocytes
M-CSF (also called CSF-1)	Stimulates production, activation, and proliferation of monocytes and macrophages
GM-CSF	Stimulates production and activation of neutrophils, eosinophils, and macrophages
G-CSF	Stimulates production and activation of neutrophils
Stem cell factor	Stimulates production of all hematopoietic progenitor cells
Erythropoietin	Stimulates production of red blood cells
Leukemia inhibitory factor	Inhibits differentiation of embryonal stem cells Induces acute phase responses Stimulates megakaryocyte and platelet production Stimulates differentiation of Ml leukemic cell line
Thrombopoietin	Stimulates production of platelets

M-CSF, c-kit), multichain receptors (e.g. IL-2, IL-3, IL-6, and GM-CSF), and single-chain receptors (e.g. G-CSF). Several of the hematopoietic growth factor receptors share adaptor subunits (e.g. GM-CSF, IL-3, and IL-5 share a subunit, and these, along with the LIF oncostatin M, all appear to signal via complexes with the cell surface glycoprotein gp130).

Cytokine receptor binding has proved to be a complex and interesting process. IL-2 binds to either of two receptor chains (α or β) with relatively low affinity: K_D3 and 70 nM, respectively. This low affinity

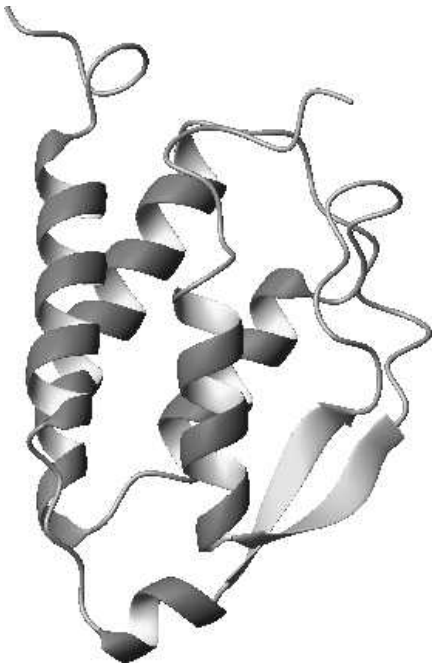

Fig. 3 The three-dimensional structure of GM-CSF illustrates the typical four-helix bundle found in many of the hematopoietic regulators.

binding does not stimulate cells. However, if both the α- and β-chains are present as a complex, the IL-2 binds with high affinity (K_D5 pM) and stimulates T-cell proliferation. The β-chain also associates with another cell surface protein called the γ-chain, which can increase the affinity of the β-chain for IL-2. The highest affinity state of the IL-2 receptor is achieved when the $\alpha\beta\gamma$ complex forms (K_D2 pM). The β- and γ-chains also complex with the IL-15 receptor to form the functional complex for IL-15 signaling, and the γ-chain complexes with the IL-4 receptor to form the high affinity IL-4 binding complex.

The IL-2 receptor binding subunits do not encode intracellular kinases; however, upon binding of IL-2, cytoplasmic tyrosine kinases in the *src* family are activated. In particular, *lck* associates with the IL-2 receptor complex, but it is still not clear whether the physical association is required for the signaling process. The γ-chain cytoplasmic region appears to be essential for activating the *src* family kinases and for stimulating the pathways leading to c-*fos* and c-*jun* expression.

Interleukin 6 binds to a specific receptor on the cell surface (IL-6Rα), but this interaction is insufficient for signaling. Once formed, the IL-6:IL-6Rα complex binds to another cell surface protein, gp130, and the trimer self-associates to form the hexameric signaling complex. gp130 also acts as the signal transduction receptor for ciliary neurotrophic factor (CNTF), LIF, and oncostatin M.

The initial signaling events stimulated by the (IL-6:IL-6Rα: gp130)$_2$ complex involve the activation of the *JAK* kinase enzymes. It is not clear whether *JAK* is associated with gp130 before the signaling complex forms, but after binding of the IL-6:IL-6Rα complex and aggregation, the *JAK* kinase is activated and phosphorylates the receptor, as well as *JAK* and *STAT* (p91). Phosphorylation of the *STAT* occurs via the *JAK* kinase after the *STAT* binds to the *JAK*-phosphorylated gp130. Once phosphorylated, *STAT* is released from the receptor and associates with a smaller protein (p48) and translocates to the nucleus, where it acts as a transcriptional regulator. Similar activation systems operate in response to many of the cytokines (e.g. growth hormone, epo, interferons, IL-3, GM-CSF, and G-CSF).

Interestingly, the cytokine/*JAK*/*STAT* signaling system is also regulated negatively. A phosphatase competes for binding to specific *JAK* phosphorylation sites on the receptor. Once bound, the phosphatase removes the phosphate from the *JAK*

kinase and deactivates the enzyme. A mutant form of the epo receptor that lacks the hematopoietic cell phosphatase-binding site has been discovered. In these people, the *JAK* kinase remains activated and associated with the epo receptor, leading to an increase in red blood cell production.

4 Perspectives

The biological action of a particular growth factor will be dependent on the differentiation state of the target cell, the presence of other growth factors, and/or the existence of cell–cell contacts (see Fig. 2). Cell–cell contacts and/or multiple growth factors acting early in many cell production pathways appear to be required to induce self-renewal of the tissue-specific stem cells. In a number of tissue systems, the presence of particular growth factors is essential to maintain cell viability at all stages of the differentiation process. If the growth factor concentration decreases, many of the immature cells will die. Mature cells usually have a definite lifetime before disintegrating; however, the functional activity of many mature cells can be activated by growth factors; for example, GM-CSF and G-CSF will prime mature neutrophils to kill bacteria more effectively.

A number of pathological responses involve excess stimulation of growth factor systems: psoraisis, inflammation, arthritis, neurodegenerative diseases, and cancer. As our understanding of these growth factor/receptor systems increases, it is becoming possible to design signaling therapeutics to treat these diseases.

Keywords

Catalases
Heme enzymes that both oxidize and reduce H_2O_2.

Cytochrome c Oxidase or CCO
The terminal oxidase in mitochondrial respiration. Electrons are transferred through the mitochrondrial electron transfer system and the final acceptor is CCO. CCO receives electrons from cytochrome *c* and uses these electrons to reduce oxygen to water. The energy released by this process is used to pump protons across the mitochondrial membrane, which drives the synthesis of ATP.

Cytochrome P450
A large group of heme enzymes that use an O_2-derived O atom to hydroxylate a variety of different compounds. These enzymes provide one of the primary means for detoxification of various foreign molecules that are concentrated in the liver. Most drugs are metabolized by the P450 system.

Heme
One of the most abundant and widely used prosthetic groups in biological systems. The heme iron can serve to bind and store O_2 as in the globins, can transfer electrons

between proteins by cycling between the Fe^{2+} and Fe^{3+} redox states, and can participate in breaking the O−O bond and storing peroxide or O_2-derived oxidizing equivalents in the heme group and surrounding proteins for the purpose of carrying out redox transformations of various substrates.

Heme Oxygenase
The enzyme that initiates the oxidation and breakdown of heme.

Heterolysis and Homolysis
This refers to the way the peroxide O−O bond breaks. Homolysis generates two hydroxyl radicals, $HO^{\cdot}$. Heterolysis generates two ions, HO^{-} and HO^{+}. Most heme enzymes use heterolysis.

Nitric Oxide Synthase or NOS
Nitric Oxide Synthase catalyzes the oxidation of the common amino acid, L–arginine, to nitric oxide (NO) and L–citrulline. NO is one of the most potent signaling molecules in biology. NO exerts its effects on the cardiovascular, immune, and neuronal systems.

Peroxidases
Heme enzymes that utilize peroxides, usually H_2O_2, to oxidize other molecules. The most well-known peroxidases oxidize small aromatic alcohols.

Enzymes that contain the heme prosthetic group include a large number of proteins found in nearly all biological systems. As used in this article, heme enzymes are defined as enzymes that catalyze the oxidative chemical transformation of a substrate. A good deal is now known about structure–function relationships in heme enzymes, primarily because the heme prosthetic group exhibits easily detectable spectroscopic properties that enable various intermediates to be studied by a variety of spectral methods. In addition, there now are a large number of known crystal structures. Perhaps the most intriguing aspect of heme enzymes is how the same heme group can adopt such different functions, which clearly relates to how the protein controls the chemistry of the heme group. As a result, heme enzymes have provided particularly rich systems for detailed structure-function studies.

1 Introduction

Heme (Fig. 1) is one of the most diverse prosthetic groups in biology. Some key biological functions of heme bound to proteins include (1) reversible oxygen binding and oxygen delivery to tissues; (2) electron transfer between proteins; and (3) enzyme reactions that primarily involve peroxide- or oxygen-dependent oxidation reactions. The function the heme serves

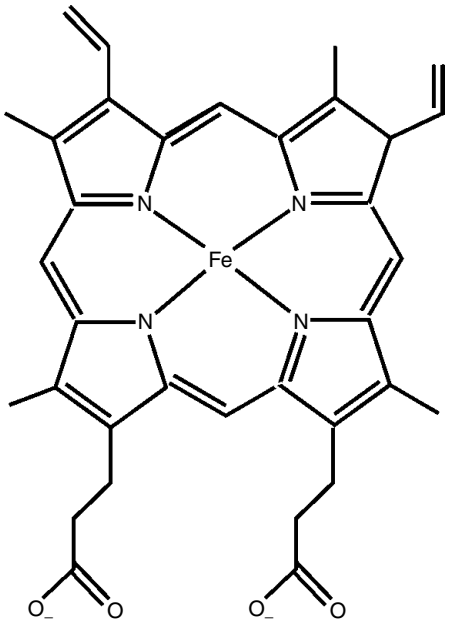

Fig. 1 The heme prosthetic group. The four-pyrrole nitrogens lie in the same plane and coordinate the heme iron. This leaves the two axial coordination positions (above and below the heme plane) available for coordinating protein side chains. In most heme enzymes, the protein contributes one axial ligand and the remaining one is either vacant or occupied by an easily dissociated solvent molecule.

depends on the surrounding polypeptide environment. The most well-known heme proteins are the globins, which both store and deliver oxygen. The heme bound to cytochromes serves primarily as an electron carrier and transfer agent where the heme iron cycles between the Fe^{2+} and Fe^{3+} oxidation states. Perhaps the most diverse use of heme is in enzyme-catalyzed reactions. Here, the heme can serve to mediate the reduction or oxidation of substrates. Although some heme enzymes can catalyze reductive reactions, the most well-known heme-containing enzymes are those that catalyze oxidation reactions and use either oxygen or peroxide as the oxidizing agent. In either case, one role of the heme is to coordinate oxygen or peroxide to the heme iron that helps to promote cleavage of the O—O bond (Fig. 2). The oxidizing power of the oxygen or peroxide ligand is thus stored at the heme site where it can be utilized to carry out specific hydroxylation or oxidation reactions. A small subset of heme enzymes utilize inorganic molecules such as hydroxylamine as oxidants. In this article, the focus is on the heme enzymes for which crystal structures have been determined.

2 Peroxidases

2.1 Introduction

Heme peroxidases occur throughout the biosphere and catalyze the oxidation of various substrates at the expense of peroxide. Peroxidases are involved in plant growth hormone metabolism, the production of thyroxine, neutrophil-mediated detoxification reactions, prostaglandin biosynthesis, and lignin degradation. While peroxidases are found in plants, animals, and microorganisms, the most thoroughly understood are nonmammalian heme peroxidases. On the basis of sequence alignments, and now crystal structures, the nonmammalian peroxidases have been divided into three classes: intercellular (Class I), extracellular fungal (Class II), and extracellular plant peroxidases (Class III). The extracellular enzymes are glycosylated, and in the case of Class III enzymes, there often are many isozymes with varying

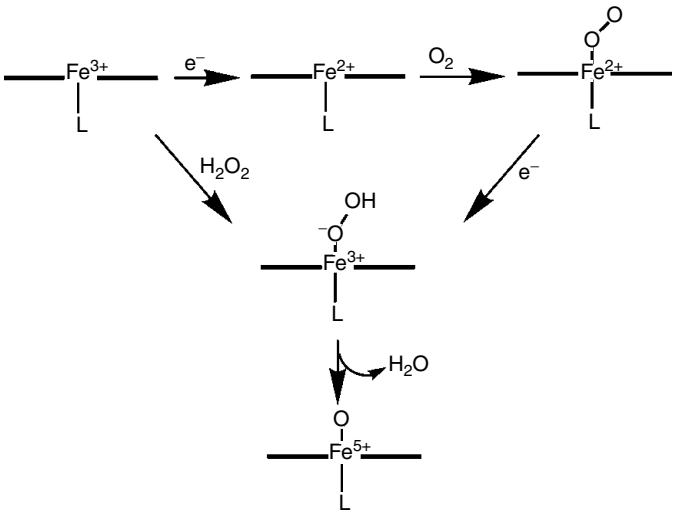

Fig. 2 A generic heme enzyme mechanism. The heme iron must first be reduced from Fe^{3+} to Fe^{2+} since molecular oxygen, O_2, binds only to the Fe^{2+} form of heme iron. Once the $Fe^{2+}-O_2$ complex is formed, a second electron transfer effectively leads to reduction of O_2 to the peroxide level. In most cases, this accompanied by protonation of the Fe-linked peroxide. At this stage, the peroxide O–O bond is cleaved, leaving behind an oxygen with only six valence electrons, a potent oxidizing agent. Exactly how the oxidizing equivalents are stored differs from one enzyme to the next, but effectively, the system behaves as if the iron is now in the Fe^{5+} oxidation state. The oxidizing power of the $Fe^{5+}-O$ center is utilized to carry out the required oxidative transformations.

degrees of glycosylation. The nonmammalian heme peroxidases are mostly single polypeptide chains in the range of 30 000–40 000 Da and contain a single ferric protoporphyrin IX as the prosthetic group. The extracellular peroxidases contain two calcium-binding sites and at least four disulfide bonds, presumably for the additional stability required of secreted enzymes.

There is a wealth of structural information available on peroxidases because several crystal structures have been solved. This, coupled with the cloning and expression of several peroxidases in recombinant systems, has opened the way for the use of protein-engineering methods to study structure–function relationships.

2.2 Catalytic Cycle

The overall peroxidase cycle occurs in three distinct steps.

$$Fe^{3+}P + H_2O_2 \longrightarrow \underset{\text{Compound I}}{Fe^{4+}-O\ P^{\bullet}} + H_2O \quad (1)$$

$$Fe^{4+}-O\ P^{\bullet} + S \longrightarrow \underset{\text{Compound II}}{Fe^{4+}-O\ P} + S^{\bullet} \quad (2)$$

$$Fe^{4+}-O\ P + S \longrightarrow Fe^{3+}P + H_2O + S \quad (3)$$

In step 1, the peroxide removes two electrons from the enzyme to give what is called Compound I. In doing so, the peroxide O−O bond is broken, giving water, and the second peroxide-derived oxygen atom remains coordinated to the iron. The iron-linked oxygen contains only six valence electrons and, hence, needs two more to give the complete complement of eight valence electrons. As a result, this oxygen is a potent oxidizing agent. One electron is removed from the iron to give the oxy–ferryl intermediate ($Fe^{4+}-O$), and a second electron is removed from the porphyrin (P in the above scheme) to give a porphyrin π cation radical. In some peroxidases, an amino acid side chain is oxidized to a radical rather than the porphyrin. The formation of Compound I is normally quite easy to follow since the resting enzyme is red/brown in color, while Compound I is green. In step 2, the porphyrin radical is reduced, giving a substrate radical $S^{\cdot}$. Owing to porphyrin reduction, Compound II is no longer green but red. Finally, in step 3, Compound II is reduced by a second substrate molecule. In plant peroxidases, the substrates normally are small aromatic molecules, and once substrate radicals form, they dimerize or disproportionate in nonezymatic reactions.

2.3 Crystal Structures

Several peroxidase structures are now known. All classes of peroxidases exhibit a similar three-dimensional structure, and a representative example is shown in Fig. 3. Although the sequence identity can be low (≈15%) between peroxidases, the crystal structures show a very similar fold independent of sequence homology

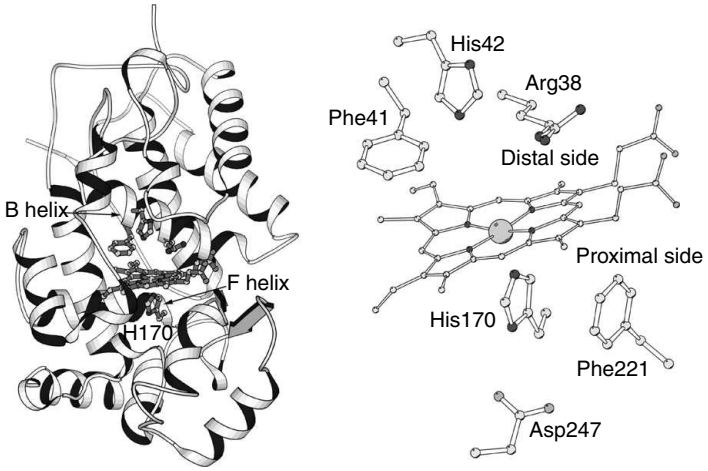

Fig. 3 The crystal structure of horseradish peroxidase or HRP taken after Gajhede et al. (1997). The heme is embedded between two helices, F and B. The F helix provides one axial heme ligand, His170. The region surrounding His170 is called the proximal pocket. The opposite side of the heme is called the distal pocket and is where the substrate, peroxide, binds. The distal helix B provides conserved side chains, His42 and Arg38, that are essential for catalysis. His42 and Arg38 are called the distal histidine and distal arginine.

or phylogenetic origin. This underscores an important ''rule'' in structural biology: tertiary structure is far more conserved than is primary structure. All the various peroxidases consist of a 10-helix core, two of which, the B and F helices, sandwich the heme in place. The various peroxidases differ in structure primarily on the surface. For example, Class III peroxidases have two additional helices on the surface (F′ and F″) where cytochrome *c* peroxidase (CCP) has a beta structure. It is thought that these additional helices in the Class III enzymes may play a role in substrate binding.

2.4 Active Site Structures

Not surprisingly, the active site of heme peroxidases is highly conserved (Fig. 3). The proximal pocket contains the histidine ligand coordinated to the heme iron. The histidine ligand donates an H bond to the conserved aspartic acid. This interaction is thought to impart a greater imidazolate character to the histidine ligand resulting in a partial negative charge on the histidine that can stabilize the Fe^{3+} state of the heme. This is one reason why peroxidases exhibit a lower redox potential in the Fe^{3+}/Fe^{2+} couple than the globins, even though both the globins and peroxidases use a histidine ligand. Directly adjacent to the histidine ligand, most peroxidases have an aromatic residue stacked parallel to and in contact with the histidine ligand. This residue is phenylalanine in most peroxidases but tryptophan in the two known Class I peroxidase structures, CCP and ascorbate peroxidase (APX). For the class I peroxidases, the tryptophan indole ring N atom donates an H bond to the conserved proximal aspartic acid.

On the opposite, distal side of the heme, the B helix provides key catalytic residues. The distal histidine and arginine are thought to operate in concert to help cleave the peroxide O−O bond. Stacked parallel to the distal heme surface is a conserved aromatic residue that is phenylalanine in known crystal structures except for the Class I peroxidases, which use tryptophan.

2.5 Catalytic Mechanism

Most of the effort in understanding the peroxidase mechanism has centered on the formation of Compound I. The distal histidine operates as an acid/base catalyst by removing a proton from the peroxide O atom directly linked to the iron (Fig. 4) and delivering it to the distal peroxide O atom. The net result is heterolytic fission of the peroxide O−O bond. This leaves behind an ''oxene'' O atom that contains only six valence electrons – a potent oxidant. The oxene O atom removes one electron from the iron to give Fe^{4+} and one from a neighboring organic group, normally the porphyrin. The crystal structure of Compound I shows that the distal arginine swings in to H-bond with the iron-linked oxygen atom. This may account in part for the stability of the Fe^{4+}−O center in Compound I.

The formation of Compound I is fast, with a second-order rate between 10^7–10^8 $M^{-1}s^{-1}$ for most heme peroxidases. Site-directed mutagenesis has been used to probe this mechanism by making amino acid substitutions of key catalytic groups in the active site. Changing the distal histidine to leucine lowers the rate of Compound I formation by 10^5, demonstrating that the distal histidine is, indeed, a critical residue. Somewhat surprisingly, the nature of the proximal ligand was

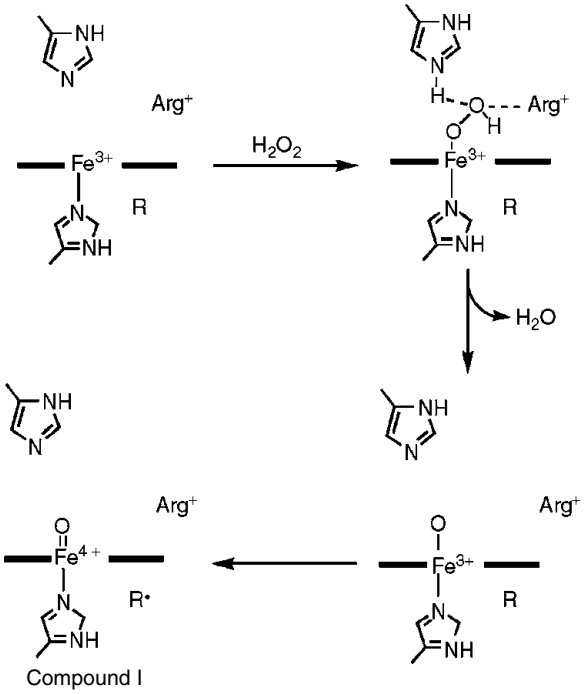

Fig. 4 The mechanism of Compound I formation. The peroxide binds to the heme iron, and one peroxide proton is transferred to the distal histidine and delivered to the leaving peroxide O atom. Precise transfer of the peroxide proton by the distal histidine ensures rapid and specific heterolytic cleavage of the O—O bond. Fe^{3+}—O is only a hypothetical intermediate and rapidly picks up two electrons, one from the iron to give Fe^{4+} and another from either the heme or a nearby amino acid side chain to give the R• radical. Reduction of R• by a substrate molecule leaves behind $Fe^{4+} = O$, which is called Compound II.

found not to be important for Compound I formation since a glutamine replacing the proximal histidine affected only the stability of Compound I and not the rate of formation.

An intriguing feature of peroxidases is how the protein controls where oxidizing equivalents are stored. In all peroxidases, one peroxide-oxidizing equivalent is stored on the iron, thus converting Fe^{3+} to Fe^{4+}. In nearly all peroxidases, the second oxidizing equivalent is stored on the heme as a porphyrin cation radical. The one exception is CCP, where Trp191 stores the second peroxide-oxidizing equivalent as a cationic radical. Trp191 occupies the equivalent position of Phe221 in horseradish peroxide (HRP) (Fig. 3). At first, it was thought that the reason CCP has a tryptophan radical is that tryptophan is easier to oxidize than the corresponding residue in most other heme peroxidases, phenylalanine. However, the structure of APX showed that APX has a tryptophan

equivalent to Trp191 in CCP, yet APX forms the traditional porphyrin cationic radical. This has lead to detailed studies using mutagenesis, crystallography, spectroscopy, and theoretical calculations to try and understand how CCP preferentially stabilizes a tryptophan radical rather than a porphyrin radical. The answer appears to be a combination of subtle structural differences resulting in an electrostatic stabilization of the extra positive charge on the tryptophan cation radical. For example, the electronegative S atoms of two mionine residues near the tryptophan radical site in CCP appear to help stabilize the tryptophan radical.

2.6 Enzyme Substrate Complexes

All the known heme peroxidase structures show that one heme edge is accessible to small aromatic molecules that are typical peroxidase substrates. It generally is thought that small substrates interact at this site and deliver electrons directly to the heme, resulting in reduction of the Compound I porphyrin radical or Compound II $Fe^{4+}-O$ center. Nevertheless, there is no direct structural evidence for this view. To date, the structure of only a limited number of heme peroxidase–substrate complexes are known. Manganese peroxidase oxidizes Mn^{2+} to Mn^{3+}, and in a complex with dicarboxylic acids, the Mn^{3+} operates as a diffusible oxidant of lignin. The crystal structure of manganese peroxidase shows that Mn^{2+} coordinates with protein carboxylates and one heme propionate. In APX, the ascorbate binds near the same heme edge very near to where Mn^{2+} binds in manganese peroxidase (Fig. 5) but is closer to the surface and does not come directly into contact with the heme propionate. Cytochrome *c* peroxidase is unusual amongst the known heme peroxidase structures since its substrate is another protein, cytochrome *c*. The crystal structure of the three substrate–peroxidase complexes are shown in Fig. 5.

2.7 Di-heme Peroxidases

Various bacteria produce peroxidases that contain two hemes and oxidize cytochrome *c* as follows:

$$2\text{cyt.c}(Fe^{2+}) + H_2O_2 + 2H^+ \longrightarrow 2\text{cyt.c}(Fe^{3+}) + 2H_2O \qquad (4)$$

The two hemes (Fig. 6) have been designated low-potential (LP) and high-potential (HP). The HP heme is hexacoordinate, with histidine and metionine residues serving as the axial heme ligands. This heme is the entry point for electrons from the reducing substrate. The most well-understood di-heme peroxidase is from *Pseudomonas aeruginosa*, and the proposed mechanism is shown below.

$$\underset{\text{high}}{Fe^{2+}}\ \underset{\text{low}}{Fe^{3+}} + H_2O_2 \longrightarrow \underset{\text{high}}{Fe^{3+}}\ \underset{\text{low}}{Fe^{4+}-O} + H_2$$

Compound I

$$\underset{\text{high}}{Fe^{3+}}\ \underset{\text{low}}{Fe^{4+}-O} + e^- \longrightarrow \underset{\text{high}}{Fe^{3+}}\ \underset{\text{low}}{Fe^{3+}} + H_2O$$

Compound II

$$\underset{\text{high}}{Fe^{3+}}\ \underset{\text{low}}{Fe^{3+}} + e^- \longrightarrow \underset{\text{high}}{Fe^{2+}}\ \underset{\text{low}}{Fe^{3+}} \qquad (5)$$

Compound II

One of the more interesting features of this mechanism is that the enzyme is inactive unless the HP heme iron is first

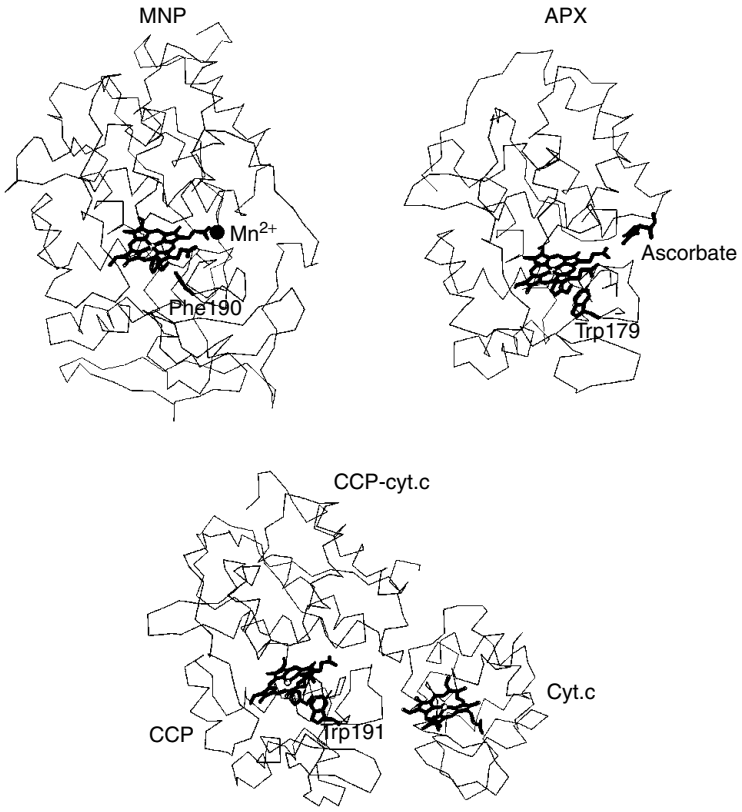

Fig. 5 Crystal structure of three peroxidase–substrate complexes. In MNP-manganese peroxidase, the substrate, Mn^{2+}, is directly coordinated to one of the heme propionate carboxyl groups. Once Compound I is formed, the electron from Mn^{2+} very likely transfers to the heme via the heme propionate. In APX, the ascorbate binds (taken from Sharp et al. (2003)) in a position very similar to Mn^{2+} in MNP except the ascorbate does not interact directly with the heme propionate. Instead, the negatively charge ascorbate interacts with surface positive charges. The structure of the noncovalent complex formed between CCP and cytochrome *c* taken from Pellitier & Kraut also is shown. The cytochrome *c* heme edge directly contacts a section of the polypeptide that contains Trp191. Trp191 forms a radical in Compound I and is known to be essential for activity. The prevailing view is that the electron from cytochrome *c* is delivered to the Trp191 radical.

reduced from Fe^{3+} to Fe^{2+}. However, a closely related di-heme peroxidase from another bacteria, *Nitrosomonas europaea*, does not require reduction of the HP heme. That this is actually a rather intriguing difference became evident once the crystal structures were solved (Fig 6).

As expected from sequence homology, the structures are very similar. Each enzyme contains approximately 300 residues folded into two distinct domains. These are designated as the HP and LP domains in Fig. 6. The most interesting difference is in the LP domain around the LP heme.

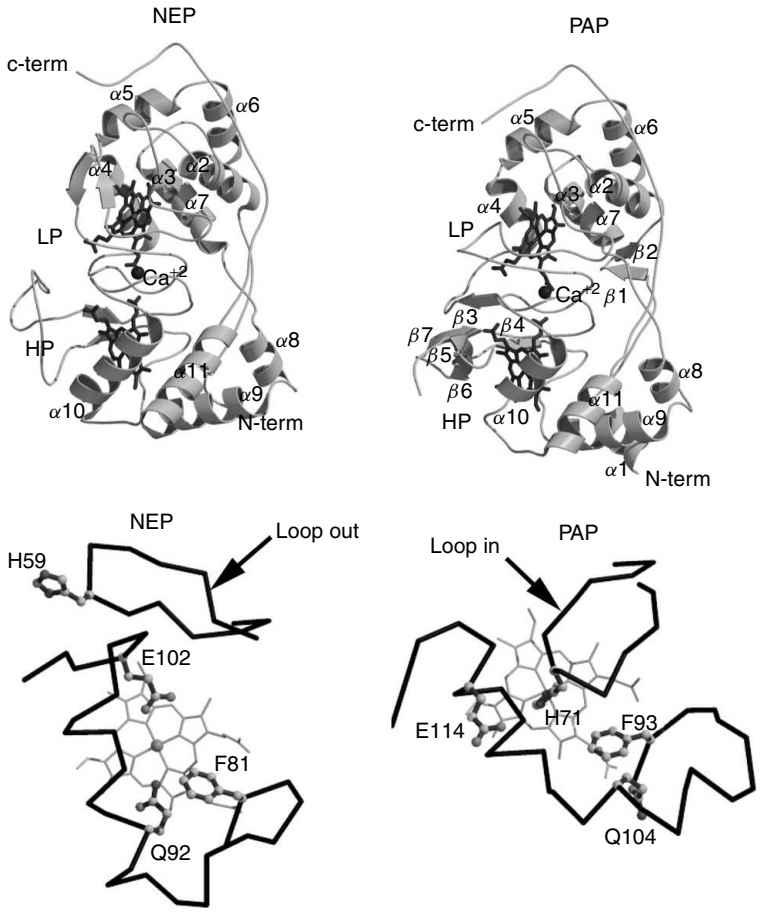

Fig. 6 Structure of two di-heme peroxidase, one from *Pseudomonas* (PAP) and one from *Nitrosomonas* (NEP). The region around the LP is shown in detail. Note than in NEP, the axial coordination position of the LP heme is available for reaction with peroxide. However, in PAP the axial coordination position is tied up with His71. Therefore, His71 must first dissociate from the heme before peroxide and react with the LP heme. This change is triggered by reduction of the HP heme by an unknown mechanism.

As shown in Fig. 6, the distal pocket where peroxide will interact with the heme iron has His71 coordinated to the heme iron in the *Pseudomonas* enzyme. However, in the *Nitrosomonas* enzyme the corresponding Histidine residue, His59, is pointing out and away from the heme pocket. Both structures are in the fully oxidized state, suggesting that in the oxidized state the *Nitrosomonas* enzyme is active, while the *Pseudomonas* enzyme is inactive. This is supported from solution biochemistry studies since the *Nitrosomonas* enzyme is fully active when both the LP and HP heme irons are in the Fe^{3+} state. However, in the *Pseudomonas* enzyme, the HP heme iron must first be reduced to the Fe^{2+} state before the LP can react with peroxides. It

therefore appears that reduction of the HP heme leads to dissociation of the His71 ligand in the LP heme, which makes available the LP heme distal pocket for reaction with peroxide. Presumably, the active forms of the LP heme in the *Pseudomonas* enzyme now look like the LP distal pocket in the *Nitrosomonas* enzyme. The remarkable aspect of this conformational change is that the introduction of a single electron into the HP heme results in the rupture of a histidine–Fe bond in the LP heme and a large rearrangement of the entire distal pocket. How this happens remains unknown.

Another interesting feature of these structures is that the peroxide-binding pocket does not contain a distal catalytic histidine as do other peroxidases. Instead, a glutamic acid residue (Glu102 in the *Nitrosomonas* and Glu114 in *Pseudomonas*, Fig. 6) is situated in a position to serve as an acid–base catalyst.

2.8 Other Heme Peroxidases

While the nonmammalian heme peroxidases have received most of the attention, the diversity of heme-containing peroxidases is very large. Mammals produce well-known peroxidases like myeloperoxidase, lactoperoxidase, and thyroid peroxidase. While these peroxidases contain heme and have active sites similar to the nonmammalian heme peroxidases, these enzymes are larger and have different three-dimensional structures. The most well understood is myeloperoxidase. The function of myeloperoxidase in white blood cells and the related eosinophil peroxidase is to oxidize halides and thiocyanate ions to produce HOCl, HOBr, and HOSCN – potent antipathogen oxidizing agents. The marine worm *Amphitrite ornata* produces a dehalogenating heme-containing peroxidase. *Mycobacterium tuberculosis*, the causative agent of tuberculosis, produces a heme catalase/peroxidase that can metabolize the most widely used antituberculoses drug, isoniazid. Strains resistant to isoniazid have a point mutation in the catalase/peroxidase, which implicates the peroxidase as a drug activator.

2.9 Catalase

Catalases catalyze the breakdown of toxic H_2O_2 to water and molecular oxygen.

$$2H_2O_2 \longrightarrow H_2O + O_2 \qquad (6)$$

Catalases are tetrameric proteins with one heme per monomer. Tyrosine rather than histidine serves as an axial heme ligand (Fig. 7). Like peroxidases, catalases contain a catalytically important distal histidine, but in catalases, this histidine lies parallel to the heme plane rather than perpendicular to it as seen in peroxidases. Because catalases both oxidize and reduce H_2O_2, it is not possible to study intermediates using H_2O_2. However, it has been possible to generate the Compound I intermediate using hydroperoxides, ROOH, since hydroperoxides cannot reduce Compound I.

The general acid–base catalytic mechanism proposed for catalase (Fig. 7) is quite similar to that proposed for peroxidases. Again, the distal histidine (His75, Fig. 7) serves to transfer a proton from the iron-linked O atom to the distal O atom. The function of Asn148 appears to be primarily in helping to orient the peroxide as well as to donate an H bond. Catalases differ from peroxidases in that a second peroxide molecule reduces Compound I, thus generating molecular oxygen and water.

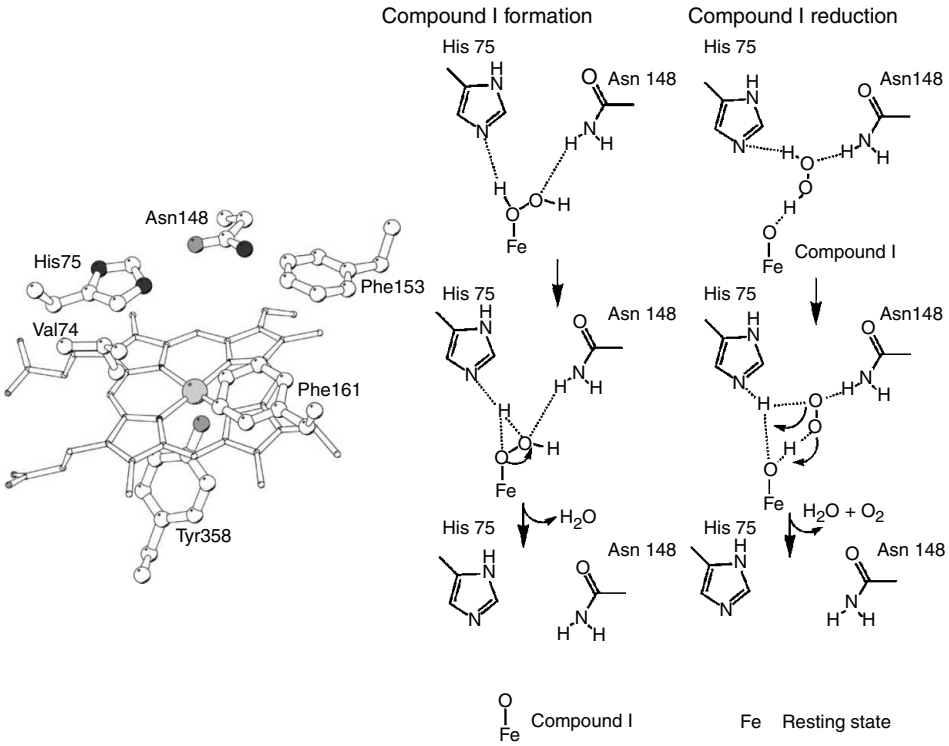

Fig. 7 The catalase active site structure and proposed mechanism. Catalase uses a tyrosine as an axial ligand rather than histidine as in peroxidases. The distal pocket contains histidine but unlike peroxidases, the histidine lies parallel to the heme, not perpendicular. Even so, the histidine can serve the same acid–base catalytic function as proposed for peroxidases. The unique feature of catalases is that peroxide is both oxidized and reduced. The first peroxide molecule is reduced to give Compound I, but the second peroxide is oxidized to give O_2.

3
Cytochrome P450

3.1
Introduction

Cytochromes P450 catalyze the hydroxylation of a vast array of molecules in the following reaction

$$\mathrm{R{-}}H + \mathrm{O_2} + \mathrm{NADPH/NADH} + 2\mathrm{H^+} \Longrightarrow \mathrm{R{-}OH} + \mathrm{H_2O} + \mathrm{NADP^+/NAD^+}. \quad (7)$$

Cytochromes P450 occur throughout the biosphere, and even prior to the current genome era, a large number of *P450* genes had been identified, making this one of the most widespread and diverse biocatalysts. Since then, the various genome projects have revealed an astonishingly large number of *P450* genes. Humans have approximately 57 expressed P450s, while *Arabadopsis* has 273 P450s. Given such a large number of P450s, it is not too surprising that P450s participate in a wide array of biological functions where hydroxylation of organic compounds are

required. For example, P450s participate in the metabolism of sex hormones, vitamin D, and bile acids in mammals; ecdysones in insects; and terpenes in plants. P450 monooxygenase systems also participate in the metabolism of a variety of drugs and other xenobiotic substances. That is, foreign substances, such as drugs, are concentrated in the liver where a variety of P450s serve to hdyroxylate these potentially toxic molecules. Hydroxylation renders such molecules more soluble for easier excretion from the body. Thus, P450s provide one of the primary means of eliminating toxic substances. P450s also participate in the conversion of aromatic hydrocarbons into potent carcinogens. This normally involves the oxidation of an aromatic heterocycle by a P450 to an epoxide. Epoxides provide potent electrophilic centers capable of chemically modifying biological nucleophiles like DNA. P450s also are the target of certain classes of commercially useful antifungal, argochemical, and therapeutic agents.

Eukaryotic P450s are membrane–bound, and liver P450s are associated with microsomal membranes. The P450 is anchored in place by an N–terminal hydrophobic peptide and a limited number of nonpolar patches on the molecular surface. Thus, P450s can be viewed as ''floating'' on the surface of the membrane. P450s also are found in mitochondrial membranes where they normally participate in the production of essential steroids. In sharp contrast, bacterial P450s are soluble and do not have the N–terminal membrane anchor. Because the bacterial P450s are soluble and easier to produce in bacterial recombinant expression systems, much of our detailed understanding of P450s derives from studies with bacterial enzymes. Of these, the camphor monooxygenase system (P450cam) from *Pseudomonas putida* is the most well known and best understood.

3.2 Structure and Mechanism

Figure 8 outlines the P450 catalytic cycle. The enzyme binds substrate, RH, which displaces a hydroxide ion coordinated to

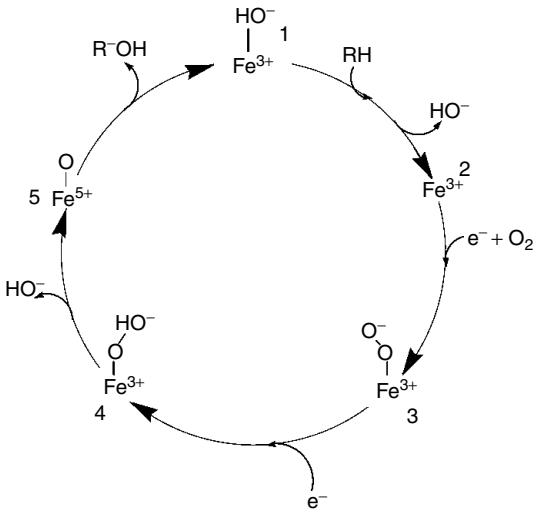

Fig. 8 The overall P450 catalytic cycle. (1) The resting enzyme; (2) substrate binds and displaces the hydroxide coordinated to the heme iron; (3) reduction of the heme iron leads to the oxy-complex; (4) protonation and reduction of the oxy-complex give the hydroperoxy complex; (5) cleavage of the peroxide O—O bond give the hypothetical Fe^{5+}—O intermediate that hydroxylates the substrate.

the heme iron. This results in an easily detected spectral shift owing to the change of the iron spin state from hexacoordinate low-spin to pentacoordinate high-spin. Reduction of the heme iron followed by oxygenation and a second electron transfer step leads to O−O bond cleavage and formation of the hypothetical Fe^{5+}−O intermediate. The Fe^{5+}−O intermediate, or its electronic equivalent, removes an H atom from the substrate followed by formation of the R−OH bond. The electron transfer reactions involve complex formation between an electron donor protein and the P450.

P450s are single polypeptide chains on the order of 40 to 50 kDa and contain a single heme (Fig. 9). Unlike the peroxidases and globins, the amino acid providing one axial iron ligand is the sulfur atom of a cysteine residue. This cysteine–heme ligation is responsible for how P450s were named since the S−Fe bond imparts unique spectral features to P450s. Early on, it was known that when a sample of liver microsomes is treated with a reducing agent in the presence of CO, the sample exhibits a strong absorption band at 450 nm, while most heme proteins maximally absorb at 420 nm. The name of the substance giving rise to this unusual spectrum was P450 (for ''pigment 450'') since, at the time, it was not known that the 450-nm material was a protein and not only a colored pigment. Even after the function of P450 was worked out, the name 450 was retained.

Several P450 crystal structures are now known and the overall fold is basically the same, even for the limited number of membrane-bound P450 structures that are known. Nevertheless, the various P450s exhibit greater structural variability than do the peroxidases. The main reason is that different P450s must bind and hydroxylate quite different substrates. Hence, the active site architecture changes quite substantially from one P450 to the next depending on substrate-binding requirements. In addition, for some P450s,

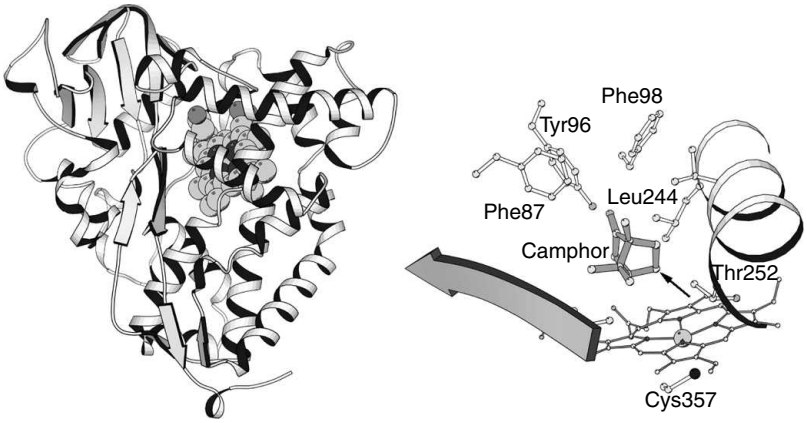

Fig. 9 The structure of the most well-known P450, P450cam from *Pseudomonas putida*. P450cam oxidizes camphor and is one step in the oxidative assimilation of camphor as a carbon source. The camphor is held in place by specific protein-substrate contacts such that the atom to be hydroxylated (indicated by the arrow) is positioned correctly for stereo- and regioselective interactions with the activated O atom linked to the iron.

there are substantial changes between the substrate-free and – bound structures presumably because the active site must open and close in order to allow substrates to enter and products to leave. Another possible reason for sealing off the active site is the need to protect the oxygen-activation chemistry at the heme site from bulk solvents. The plasticity of P450s may also be of special significance in those P450s that are required to hydroxylate a variety of molecules with seemingly little in common. From the limited knowledge now in hand, it appears that helices and loops near the entry of the active site can adapt to the size and shape of the substrate.

3.3 Electron Transfer

Most heme enzyme catalytic cycles require the input of electrons. In order to activate molecular oxygen, the heme iron must first be reduced from Fe^{3+} to Fe^{2+} since O_2 binds only to the reduced heme iron. The source of electrons is normally another protein that contains a redox active cofactor. P450s use electron donors containing either flavins or (Fe_2S_2) centers. Microsomal P450s utilize P450 reductase, which contains FMN and FAD (Fig. 10). Electrons are transferred to the FMN from NADPH *via* FAD. The path of electron flow is thus NADPH-FAD-FMN-heme. The reductase and P450 must form a complex that enables the FMN to be correctly positioned relative to the P450 heme for efficient electron transfer. There are basically two problems in understanding such reactions. First, how does the complex form? What regions of the surfaces interact and what are the dominant forces that hold the complex together? Secondly, how does the electron transfer from donor to acceptor? There is active debate on this topic. One view holds that it is sufficient to get the two redox active cofactors close enough such that

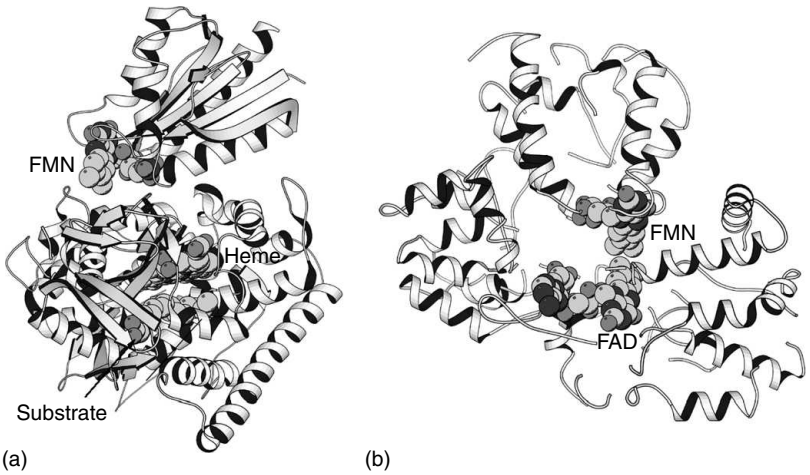

Fig. 10 The crystal structure of the FMN domain of P450BM3 complexed to the P450BM3 heme domain is shown in (a). The structure of cytochrome P450 reductase is shown in (b). The flow of electrons is NADPH-to-FAD-FMN-heme. Therefore, the FMN domain of the P450 reductase must form a complex with P450 for intramolecular electron transfer.

the electron tunnels through the protein matrix without need for a specific electron transfer path. An alternate view holds that the electron transfer proteins are ''wired'' with specific paths along the polypeptide backbone and, possibly, side chains.

To probe these questions in any detail requires crystal structures, and thus far, there is only one known structure of a P450 electron transfer complex (Fig. 10). The structure shown in Fig. 10 is that of P450BM3. This is a bacterial P450 that is the closest known bacterial P450 homologue to microsomal P450s. Like microsomal P450s, P450BM3 utilizes a FAD/FMN reductase. However, in P450BM3, the heme and flavin reductase are fused together into a single polypeptide chain giving the following modular architecture: heme-FMN-FAD. The structure of the complex shown in Fig 10 is that of P450BM3 with the FAD domain removed. The FMN is oriented down toward the P450, which allows the FMN to directly contact the P450. The FMN to heme distance is about 18 Å. In comparing this structure with that of P450 reductase (Fig. 10), an interesting puzzle arises. Note that in P450 reductase, the FMN and FAD cofactors are directly contacting one another. This structure is not compatible with the structure of the P450BM3 heme–FMN complex. In order for the FMN domain of the entire reductase to form the same type of complex observed in the P450BM3 structure, the FMN and FAD domains must move apart. The required motion must be large enough so that the FAD domain swings out of the way to allow the exposed edge of the FMN to dock on to the P450 surface. One possible scenario is that FAD delivers an electron to the FMN *via* direct contact between the flavins as seen in the crystal structure, but then the FAD rotates out of the way thus freeing the FMN to dock with the P450 and deliver its electron to the heme. How such molecular gymnastics are controlled and the precise mechanisms involved remain a mystery. Even so, the tools are in hand to probe these problems in molecular-level detail.

4
Chloroperoxidase

4.1
Introduction

The crystal structure of one heme halide peroxidase is known (Fig. 11). Chloroperoxdidase (CPO) is secreted by the mold *Caldariomyces fumago*, where it functions to chlorinate 1,3-cyclopentanedione to the natural product 2,2-dichloro-1,3-cyclopentanediol (caldariomycin). The catalytic cycle of CPO is very similar to other heme peroxidases. However, in CPO, the oxidizing power of Compound I is utilized to oxidize Cl^- ions to HOCl, and the HOCl then operates as an organic chlorinating agent. Traditional heme peroxidases cannot catalyze these reactions probably because the redox potential of Cl^- is too high. However, CPO operates at very low pHs ($\approx$3) where the redox potential and hence reactivity of Compound I may be significantly increased over other peroxidases that operate closer to the physiological pH.

CPO consists of a single 30 000-Da polypeptide, one heme, and one disulfide bond. The crystal structure shows at least 14 different sites of glycosylation. Unlike other heme peroxidases, the proximal ligand is cysteine and not histidine. Since CPO has the same cysteine–heme ligand environment as P450s, CPO exhibits spectral properties very similar to P450s. The most significant is the 450-nm

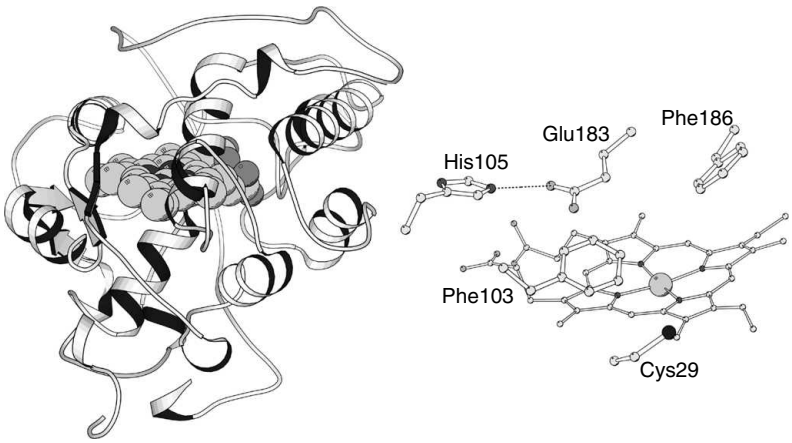

Fig. 11 The structure of chloroperoxidase (CPO). CPO combines features of P450s and peroxidase. Like P450s, the proximal axial heme ligand is a cysteine residue, and like peroxidases, the distal pocket contains polar residues that can serve a catalytic function. With CPO Glu183 serves the same function as the distal histidine in peroxidases.

band observed in the visible absorption spectrum when the enzyme is reduced in the presence of carbon monoxide to give the $Fe^{2+}-CO$ complex.

4.2 Compound I Formation

Like other heme peroxidases, CPO also reacts with peroxides to give Compound I, which contains the Fe(IV)−O center and a porphyrin π cation radical. However, unlike other heme peroxidases, CPO does not utilize a histidine residue as an acid–base catalyst. It appears instead that CPO employs Glu183 (Figs. 11 and 12) for this purpose. Glu183 is close enough to the peroxide-binding site such that the glutamic acid side chain could operate like the distal histidine in other heme peroxidases (Fig. 12). CPO thus shares properties with both P450 and peroxidases. Like P450s, CPO uses cysteine as a proximal heme ligand, but unlike P450, the distal pocket contains a potential catalytic group, Glu183. P450s instead appear to use water as the source of protons required for cleavage of the O−O bond. The more polar nature of the distal pocket in CPO due primarily to the Glu183–His104 H-bonded pair is more similar to the polar distal pocket of traditional heme peroxidases. Therefore, CPO can be said to have a P450-like proximal cysteine ligand environment while the distal peroxide-binding site is more peroxidase-like.

4.3 Reactions Catalyzed by Chloroperoxidase

Since CPO is structurally a P450-peroxidase hybrid, it is not too surprising that CPO is one of the most diverse of the known heme enzymes. In addition to operating as a chloroperoxidase, CPO exhibits activities characteristic of traditional heme peroxidase, catalase, and P450s.

$$\underset{\text{(normal function)}}{\text{Halogenation}}\ RH + H_2O_2 + Cl^- + H^+ \longrightarrow R{-}Cl + 2H_2O$$

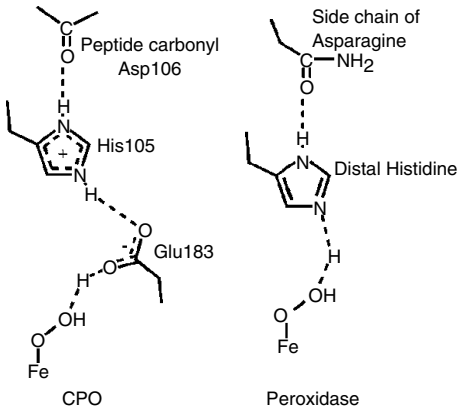

Fig. 12 The catalytic mechanism of CPO compared with traditional heme peroxidases. The glutamic acid in CPO is considered to serve the same role as the distal histidine in peroxidases.

$$\text{Dehydrogenation } 2RH + H_2O_2 \xrightarrow{\text{(heme peroxidases)}} R{-}R + 2H_2O$$

$$H_2O_2 \text{ decomposition } 2H_2O_2 \xrightarrow{\text{(catalase)}} O_2 + 2H_2O$$

$$\text{Oxygen insertion } R + H_2O_2 \xrightarrow{\text{(P450)}} R{-}O + H_2O \qquad (8)$$

Sulfoxidation and epoxidation reactions catalyzed by CPO can proceed with a high degree of enantioselectivity. Even the typical peroxidase dehydrogenation reactions can proceed with enantioselectivity, something other peroxidases cannot do. The CPO crystal structure provides some insights into these unusual functional properties. Although CPO is a helical protein, the overall fold is unique and does not have the typical peroxidase fold. In addition, the heme is accessible from the top distal surface and not the heme edge. Bracketing the distal heme pocket near the $Fe^{4+}{-}O$ center are two key phenylalanine residues, Phe103 and Phe186, and other hydrophobic groups that form a shallow pocket that is the most probable site for substrate binding (Fig. 11). The asymmetric nature of this pocket can account for the observed enantioselectivity.

5 Nitric Oxide Synthase (NOS)

5.1 Introduction

The biological significance of NO as a major signaling molecule became evident in the late 1980s, and since then, progress has been remarkable. NO was recognized as molecule of the year by *Science Magazine* in 1992, and the discovery of NO as the molecule responsible for smooth muscle relaxation was awarded the Nobel Prize in 1998. Initially, it was recognized that NO plays a key role in three separate physiological systems: cardiovascular, immune, and nervous. The NO for each system is produced by a separate isoform of nitric oxide synthase (NOS): eNOS (e = endothelial; cardiovascular system), iNOS (I = inducible; immune system), and nNOS (n = neuronal). The growing number of genomes shows that NOS is not confined to mammals but is also present in insects and bacteria. Hence, NO undoubtedly plays an important but as yet unknown

role in a large number of organisms and is perhaps a much "older" enzyme than initially thought. From the perspective of structural biology, that there are only three human NOS isoforms makes structure-based isoform-selective drug design a tractable problem.

In addition to its important role as a signaling molecule, NO is known to be involved in a number of pathological states including hypertension, septic shock, stroke, and degenerative neural diseases. In the immune system, nitric oxide was found to be linked to the ability of macrophages to kill tumor cells and fungi. Nitric oxide is a reactive free radical and either NO itself or further metabolized products such as peroxynitrite ($^{-}$ ONOO) are responsible for the killing ability of NO. In the cardiovascular system, the discovery of NO as a messenger molecule was based on the effect of NO as a metabolic breakdown product of nitroglycerin and other organic nitrates on vasodilation. In the nervous system, the effect of excitatory amino acids on the production of NO lead to the discovery that NO is involved in neural transmission systems. Recently, it has become apparent that NO acts as a neurotoxic agent in Alzheimer's disease.

Owing to the instability of NO and its potency as a messenger molecule, it is necessary to tightly regulate rapid NO production at the enzyme level for constitutively expressed NOSs, eNOS, and nNOS. Both enzymes bind Ca^{2+}–calmodulin (Fig. 13),

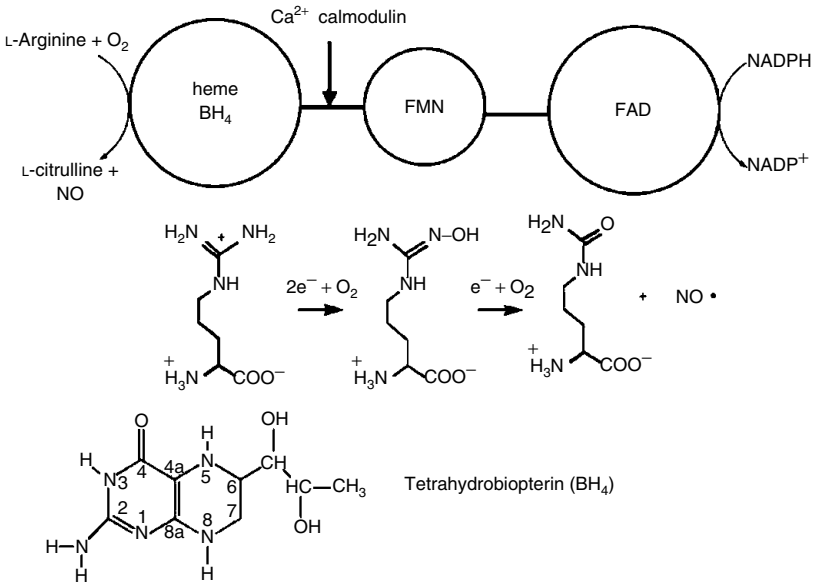

Fig. 13 NOS is a complex multidomain enzyme. Similar to P450s, electrons from NADPH-to-FAD-to-FMN-to-heme, except in NOS, the FMD/FAD reductase and heme domains are linked together in a single polypeptide chain. The linker connecting the heme and flavin domains binds the well-known regulatory molecule, calmodulin. The binding of calmodulin activates NOS by stimulating electron transfer from the flavin domain to heme by an as yet unknown mechanism. The net result is oxidation of the common amino acid, L–arginine, to citrulline and NO. A unique feature of NOS is its requirement for the cofactor, tertrahydrobiopterin (BH4).

which stimulates NOS activity and, hence, NO formation. For example, glutamate acting on the brain NMDA receptor causes the influx of Ca^{2+} that binds to calmodulin that, in turn, stimulates NO production by nNOS. In contrast, iNOS is not sensitive to Ca^{2+} even though iNOS has calmodulin tightly bound as an additional subunit. Thus, the production of NO in the immune system appears not to be controlled at the enzyme level as with eNOS and nNOS but rather in the biosynthesis of iNOS itself at the level of transcription. Why iNOS retains the ability to bind calmodulin yet remains insensitive to Ca^{2+} is unknown.

Nitric oxide exerts its effects in the vascular and neural systems by stimulating guanylate cyclase. The binding of NO to the guanylate cyclase heme iron results in cyclic cGMP production, which, in turn, results in a number of physiological effects. One such effect is neural transmission. The cardiovascular effects exhibited by NO also are mediated *via* guanylate cyclase.

5.2 Overall Structure

The modular architecture of NOS presents an especially challenging problem to structural biologists. It appears likely that NOS can adopt many conformational states depending on how the various structural modules are oriented relative to one another. The availability of various domain orientations also appears to be an essential part of NOS function. The regulatory properties of calmodulin reside in the control of electron transfer from the reductase domain to the heme domain. The most probable mechanism is a reorientation of the FMN domain such that it docks properly to the heme domain for electron transfer. While conformational heterogeneity may provide a means for controlling enzyme activity, it presents a particularly vexing problem for crystallization. As a result, crystallographers have focused on structures of the heme domain alone, which contains the active site and BH4-binding sites.

The structure of the eNOS heme domain and active site is shown in Fig. 14. The

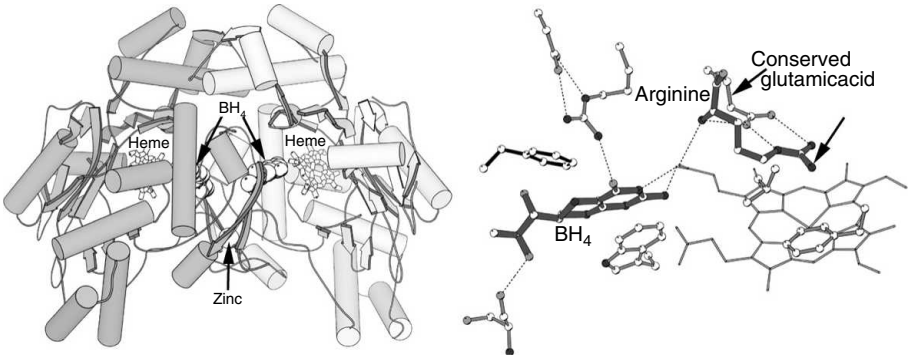

Fig. 14 Structure of the NOS heme domain. The mammalian NOS isoforms function as heme domain dimers as shown. The substrate, L–arginine, is held in place by specific H-bonding interactions. The BH4 cofactor H-bonds with the same heme propionate that H-bonds with the L–arginine substrate, which helps to understand the observed cooperativity in L–arginine and BH4 binding. It now appears that BH4 serves as a source of an electron required in activation of the iron-bound dioxygen.

structure of iNOS and nNOS also are known, but since these structures are all virtually the same with nearly identical active sites, only eNOS will be discussed in detail. NOS functions as a homodimer with the heme domain providing the dimer interface (Fig. 14). A Zn^{2+} ion lies along the dyad axis of symmetry where it is tetrahedrally coordinated to symmetrically related pairs of cysteine residues. The function of the redox inactive Zn^{2+} ion in proteins is normally structural or as a Lewis acid in hydrolytic reactions. In NOS, it appears that the main role of Zn^{2+} is to help stabilize the dimer interface. Since both BH4 molecules are bound at the dimer interface, it appears that the Zn^{2+} also helps to stabilize the BH4 site.

5.3 Active Site Structure

Also shown in Fig. 14 is the active site with the substrate, L–arginine, bound. The hydrogen-bonding environment surrounding the α-carbon position explains the selectivity for L–arginine as opposed to D–arginine. An especially important set of interactions are the hydrogen bonds between the conserved glutamic acid and L–arginine guanidinium group. This interaction helps to hold the substrate in place such that the atom to be hydroxylated sits just above the heme iron. In this regard, NOS operates in exactly the same way as P450s; that is, specific substrate-protein interactions hold the substrate in place close to the heme iron for region- and stereoselective hydroxylation. Where NOS differs most is in the strict requirement for BH4. Note (Fig. 14) that both BH4 and L–arginine hydrogen bond with the same heme propionate. This helps to explain the well-known synergy between L–arginine and BH4 binding. However, the main function of BH4 now appears to be as an electron donor to the heme iron atom during the oxygen activation reaction. With P450s, electrons derive from the flavins of P450 reductase. With NOS, however, one of the two electrons required for oxygen activation derives from BH4 giving a BH4 radical. Ultimately, the BH4 radical is re-reduced by the NOS flavins. Precisely why NOS requires this additional level of complexity in the electron transfer process compared with P450s remains unknown.

6 Heme Oxygenase

6.1 Introduction

The degradation of heme proteins results in the release of heme. Hemoglobin is the main source of heme and approximately 6 to 8 g of hemoglobin are degraded daily, thus releasing about 300 mg of heme per day. Free heme is not reutilized but instead is degraded while the iron released is stored for further use. Heme oxygenase or HO is the enzyme responsible for the breakdown of heme. HO oxidizes heme to biliverdin and CO and is the most important reaction in biological systems to generate CO (Fig. 15). Biliverdin is reduced by biliverdin reductase to bilirubin, which is then conjugated with glucuronic acid and excreted. Heme is red, biliverdin is blue–green, and bilirubin is yellow–red. This is the reason that a hematoma, or bruise, from damaged tissue changes color with time. The second product of the HO reaction, CO, also is of growing interest. To some extent, CO can mimic NO in its ability to stimulate guanyl cyclase. This, together with the cellular localization of the HO isoforms, has lead to the proposal that

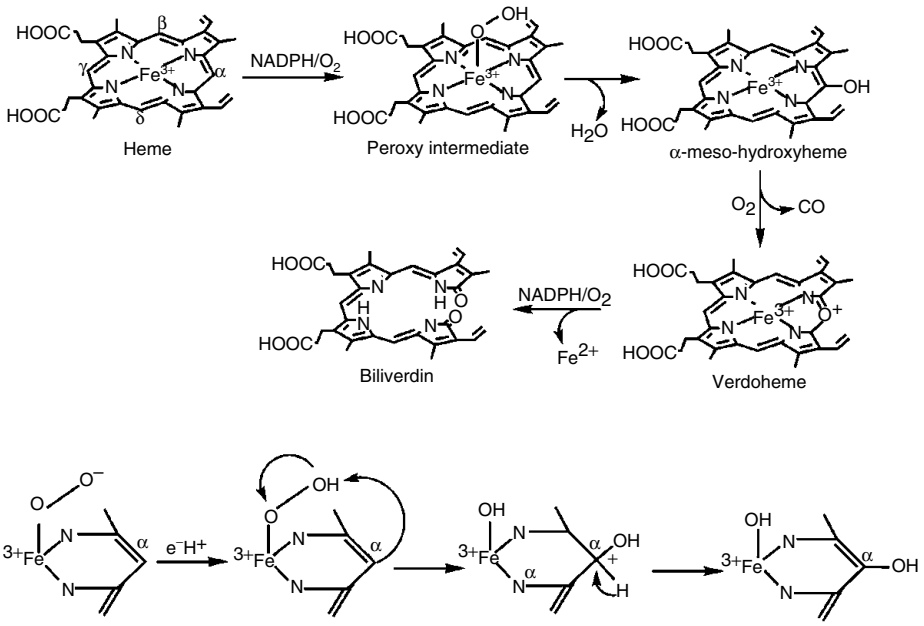

Fig. 15 The catalytic cycle of heme oxygenase. Reduction of the oxy-complex gives the peroxy-complex similar to other heme enzymes. However, unlike other heme enzymes the peroxide O—O bond is not cleaved prior to substrate oxidation. Instead, the peroxy intermediate itself serves as the hdyroxylating agent. The HO active site is structured such that only the heme *α-meso* carbon can react with the peroxy intermediate. This is followed by a series of reactions leading to the formation of biliverdin and release of CO. Details of the critical hydroxylation step are outlined.

CO may serve as an important signaling. This remains an intriguing yet controversial topic.

Humans have two HO isoforms designated HO1 and HO2. They differ primarily in tissue location and regulation. HO1 levels increase in response to oxidative stress and, like iNOS, is induced during the inflammatory response. HO1 was the first to be cloned and expressed in a bacterial recombinant expression system. Since HO1 contains a C–terminal membrane anchor segment, it first was necessary to remove the C–terminal peptide in order to generate a soluble version of HO1. Fortunately, the truncated soluble version of HO1 is fully active. The availability of large quantities of soluble recombinant HO1 has provided the basis for much of our current understanding of structure–function relationships in HO1.

6.2 Structure

At the time of this writing, the structures of three HOs have been determined: human and rat HO1 and the bacterial HO from *Neisseria meningitidis*. The structure of human HO1 is shown in Fig. 16. The enzyme is comprised of only helices and random coil and represents a novel helical fold. The heme is sandwiched between the distal and proximal helices. The proximal His25 provides one axial heme ligand. Unlike peroxidases and P450s, the heme

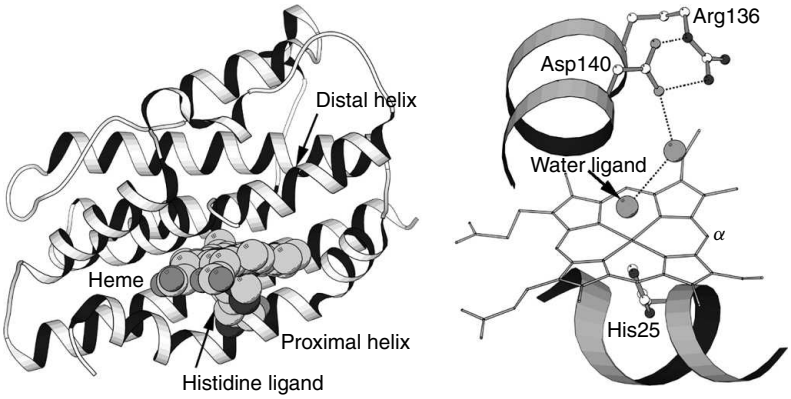

Fig. 16 The structure of human heme oxygenase-1 or HO1. The heme is relatively exposed in HO compared to other heme enzymes. This is required since heme is the substrate and hence, efficient catalysis requires both binding of substrate and ready release of product. The active site structure shows a network of H bonds involving ordered water molecules important for catalysis.

is relatively exposed in HO1. The negatively charged heme propionates are held in place by a series of positively charged amino acids.

The distal helix is of particular interest owing to several conserved glycine residues and the resulting flexibility of the heme pocket. In the crystals of human HO1 used to determine the structure, there are two molecules in the asymmetric unit. The distal helix adopts slightly different conformations in each. In one, the distal helix is further from the heme, thus giving the ''open'' conformer, while in the other molecule, the distal helix is situated closer to the heme, giving the ''closed'' conformer. This type of flexibility is required by HO since heme is a substrate; so, active site motion is required for substrate binding and product release.

6.3 Mechanism

Figure 15 provides an outline of the HO mechanism. Each of the intermediates has been identified and characterized using a variety of spectroscopic and kinetic techniques. The source of electrons required to drive the reaction are from NADPH. Reducing equivalents from NADPH are delivered to the HO heme *via* P450 reductase. Hence, like P450s, HO must form a complex with the reductase. HO differs markedly from P450 and peroxidases in that peroxide is the active hydroxylating agent. In both P450s and peroxidases, the peroxide O−O bond is cleaved, giving Fe^{3+}−O or its electronic equivalent. With these enzymes, it is the iron-linked oxygen that serves as the hydroxylating agent. As shown in Fig. 15, it is the distal peroxide O atom that forms a bond with the α-meso carbon of heme.

The first step of the reaction, hydroxylation of heme to give α-*meso*-hydroxyheme, has received the most attention. A key question is how the enzymes ensure that only the α-*meso* heme carbon is hydroxylated. The structure supports the view that the primary factor is steric. In the closed conformation, the only heme *meso*

carbon that remains available for reaction is the *α-meso* carbon. The active site provides an open pocket just above the *α-meso* carbon that is partially filled with water molecules (Fig. 16). Oxygen binding to heme prefers a bent conformation and it appears most likely that the oxygen bends toward the *α-meso* carbon, thus placing the distal O atom close enough to the *α-meso* for reaction. The bacterial HO structure also supports this view.

Another key factor is that HO uses peroxide as the hydroxylating agent rather than the Fe−O center found in other the heme enzymes. Recent mutagenesis work has shed considerable light on this issue. Changing Asp140 (Fig. 16) to other residues converts HO into a peroxidase. The mutant HO now cleaves the peroxide O−O bond, thus generating the Fe(IV)−O center, which can then oxidize traditional peroxidase aromatic phenol substrates. It appears that Asp140 and its surrounding H-bonding environment (Fig. 16) are essential for preventing cleavage of the O−O bond. One can view this as a balance between O−O bond cleavage and *α-meso* hydroxylation, with the local H-bonding environment favoring *α-meso* hydroxylation. Disruption of this network as in the Asp140 mutants tips the balance in favor of O−O bond cleavage. In addition, it appears that the Asp140-water hydrogen-bonding network helps to steer the iron-linked dioxygen toward the *α-meso* carbon. An interesting feature of the HO mechanism shared by P450s is the lack of amino acid side chains that directly interact with the iron-linked dioxygen. In both P450 and HO, water plays a key role in catalysis by serving the acid–base catalytic functions fulfilled by histidine in peroxidases.

7
Cytochrome *c* Oxidase (CCO)

7.1
Introduction

CCO is the terminal electron acceptor in eukaryotic and some bacterial respiratory systems. The enzyme catalyzes the reduction of O_2 to water by utilizing electrons from ferrocytochrome *c*. In the process, CCO pumps protons across the mitochondrial membrane thereby generating the proton motive force required for the biosynthesis of ATP. Needless to say, this is a central enzyme in bioenergetics and has been the topic of extensive investigations. CCO is a complex transmembrane enzyme consisting of several subunits. However, only subunits I and II are highly conserved in both prokaryotes and eurkaryotes and also contain the redox active centers required for the catalytic cycle. Subunit II contains the so-called Cu_A site, which is the entry point of electrons from ferrocytochrome *c*. Subunit I contains the hexacoordinate heme a, pentacoordinate heme a_3, and Cu_B. Precisely how the transfer of electrons from ferrocytochrome *c* through the various redox centers in CCO is coupled to the pumping of oc protons through CCO and across the membrane continues to be a challenging problem under active investigation.

7.2
Structure

Research on CCO took a major step forward in 1995 with the structure determination of both eukaryotic and prokaryotic CCO structures. These structures represent one of the major achievements in structural biology and have opened the way toward a molecular-level understanding of

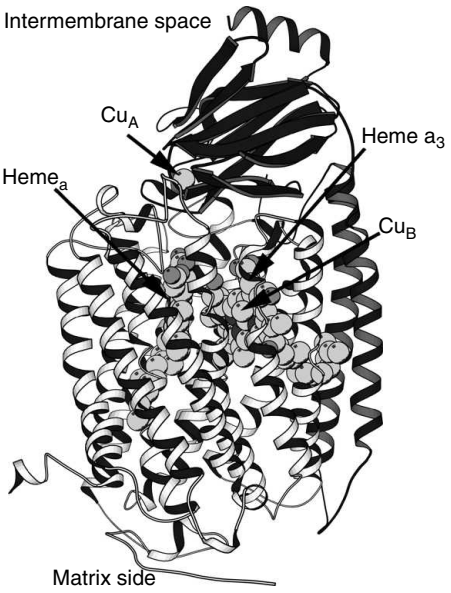

Fig. 17 The structure of mammalian cytochrome *c* oxidase showing only subunits I (light shading) and subunit II (dark shading).

one of Nature's most complex and critical biochemical processes. The structure of eukaryotic CCO is shown in Fig. 17, while Fig. 18 is a more schematic diagram illustrating the relationship between redox centers. Subunits I and II contain the redox active centers. The smaller subunit II consisting of 227 residues has a primarily β-sheet domain sitting over the top of subunit I on the surface of the membrane. The Cu_A center consists of two Cu atoms coordinated to histidine, metionine, and cysteine residues located in the subunit II β-sheet domain. Subunit II also contains two transmembrane helices that interact with helices in subunit I. The larger subunit I has 514 residues and is composed of 10 transmembrane helices. Heme a utilizes two histidine residues as axial ligands. Heme a_3 is coordinated by only one histidine. The remaining axial coordination position remains open for binding of O_2. Finally, Cu_B is coordinated by histidine residues and is situated only 4.7Å from the iron of heme a_3 (Fig. 17). A unique feature of the Cu_B site revealed by the x-ray structures is that one Cu_B histidine ligand is covalently attached to a neighboring tyrosine residue (Fig. 19).

7.3 Electron Transfer

Since electrons are delivered to CCO from ferrocytochrome *c*, it is necessary for cytochrome *c* first to form a complex with CCO. Because cytochrome *c* is a soluble protein in the intermembrane mitochondrial space, the complex must form between regions of CCO situated on the membrane surface. It is well known that electrostatic interactions dominate complex formation with positive charges on cytochrome *c* interacting with negative charges on CCO, most likely with residues in subunit II. The entry point of an electron from ferrocytochrome *c* is thus Cu_A. The rate of electron transfer is fast, on the order of 70 000 sec^{-1}. Next, the electron is transferred from Cu_A to heme A at a rate of $\approx$20 000 sec^{-1}. Finally, the electron is transferred from heme a to the site of O_2 activation, heme a_3. Since heme a and heme a_3 are close, the electron transfer very likely occurs *via* heme edges of closest approach.

7.4 O_2 Activation

A variety of sophisticated spectral methods have been utilized in an attempt to understand how O_2 is activated at the heme a_3/Cu_B center and what intermediates are formed during this process. Time-resolved

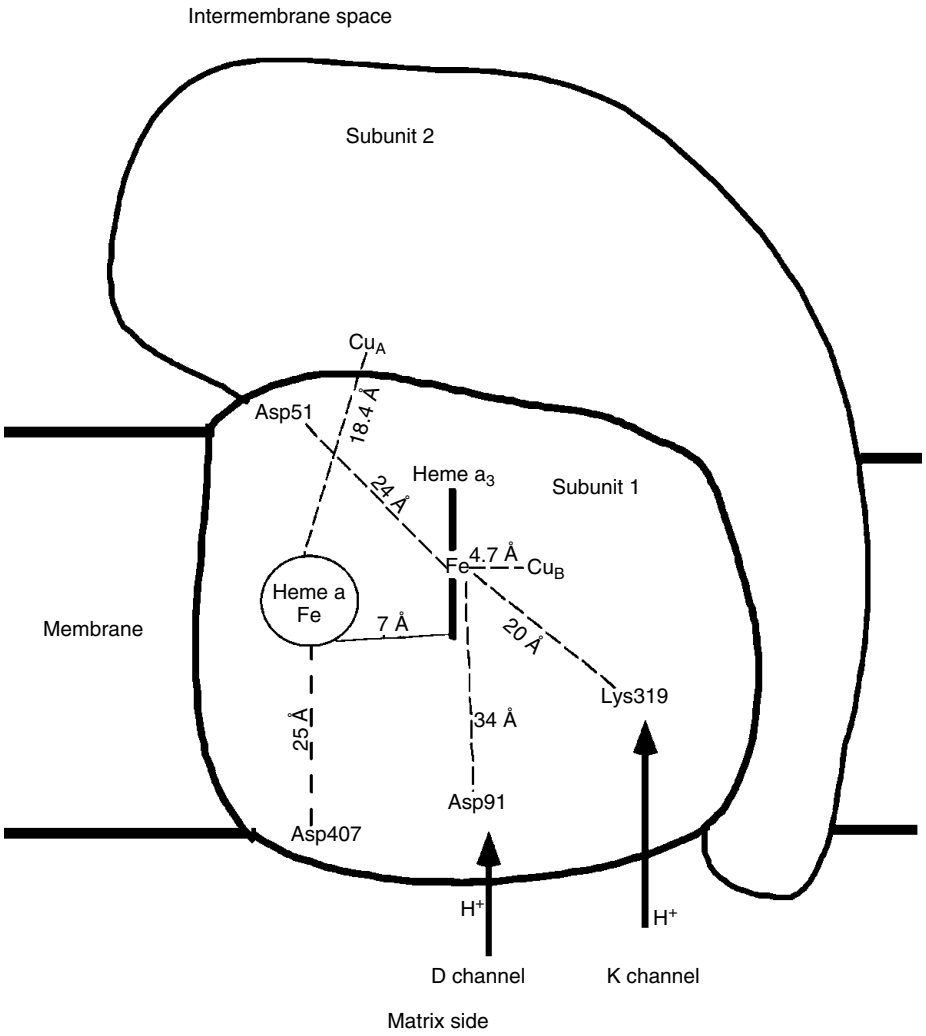

Fig. 18 A schematic diagram of cytochrome *c* oxidase. The various distances between heme and copper centers are indicated and the possible proton-pumping channels highlighted.

resonance Raman is uniquely suited to providing such structural information. In the Raman studies, the time course of various Raman bands is first resolved and then structures are assigned to these transient species. The results of these studies are summarized in Fig. 19. The a_3 heme iron must first be reduced to Fe^{2+} in order to bind O_2. The oxy–complex in Fig. 19 is shown as the Fe^{3+}–superoxide complex, which is likely the favored resonance structure. Cu_B delivers an electron to the superoxide intermediate, thus generating the peroxy-complex. As in peroxidases, the peroxide O—O bond cleaves heterolytically giving the Fe^{3+}—O hypothetical species in which the O atom has only six valence electrons and is a potent oxidizing agent

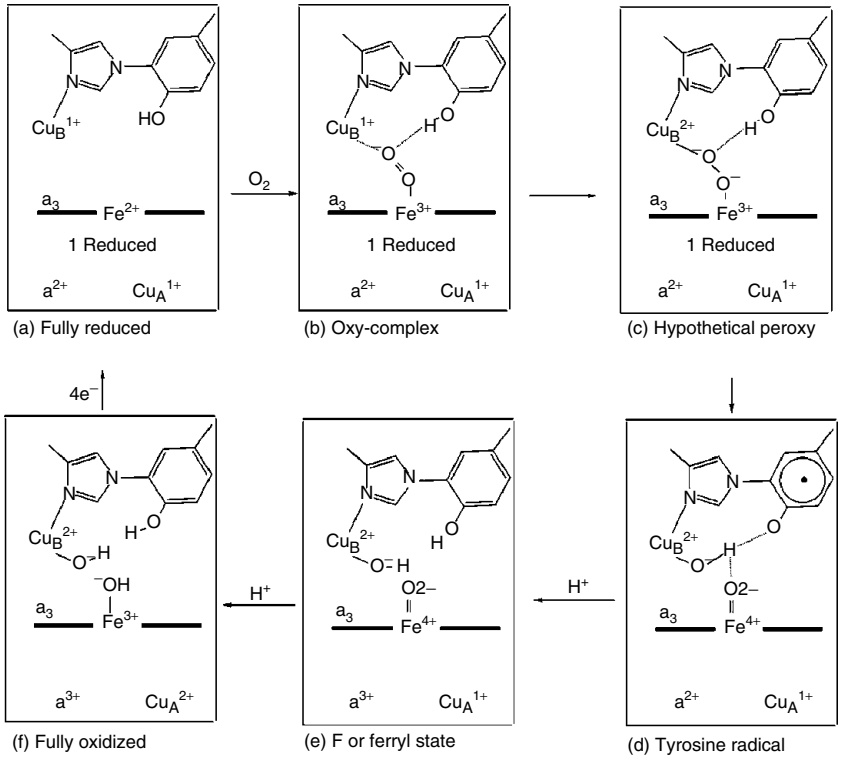

Fig. 19 Schematic representation of the cytochrome *c* oxidase (CCO) O_2 activation process taken after Proshlyakov et al. CCO has three redox active metal centers. Cytochrome *c*, the soluble electron transfer protein, delivers electrons to the two-copper Cu_A center and then to heme a. From heme a, electrons move to the binuclear heme a_3/Cu_B center where O_2 activation occurs. The fully reduced enzyme in (a) binds molecular oxygen to give the oxy-complex in (b), which is equivalent to the Fe^{3+}–superoxide complex as shown in (b). In (c), Cu_B has transferred an electron to dioxygen to give the peroxy-complex. The step from (c) to (d) results in heterolytic cleavage of the O–O bond leaving hydroxide bound to Cu_B and an oxygen atom linked to the iron. The iron-linked O atom contains only six valence electrons and is a potent oxidant. As a result, one electron is removed from the iron to give Fe^{4+} and, one from another group, which now is thought to be tyrosine, giving the structure in (d). Intermediate (d) is similar to peroxidase Compound I. Steps (d) to (e) and (e) to (f) involve intramolecular electron transfer, which gives back the resting state oxidized enzyme. The cycle begins again by reduction of (f) by ferrocytochrome *c*.

requiring two more electrons. One electron is transferred from the iron to give Fe^{4+} and the second from the tyrosine residue covalently linked to a Cu_B histidine ligand to give a tyrosine radical. Tyrosine thus serves a similar role to the porphyrin radical in peroxidase Compound I.

7.5 Proton Pumping

The mechanism just described shares similar features to peroxidases and P450s. The unique feature of CCO, however, is that the electron transfer and O_2 activation

processes are coupled to the movement of protons across the membrane. It is generally thought that CCO must have a channel that utilizes protein groups to move protons along from one proton acceptor to the next. Two primary channels, designated D and K after Asp91 and Lys319, have been the primary regions thought to provide proton channels. Site-directed mutants in channel D in bacterial CCOs results in the enzyme being trapped at intermediate four (Fig. 18).

8 Cyclooxygenase

8.1 Introduction

Prostaglandins are long chain fatty acids derived from arachidonic acid (Fig. 20). Arachidonic acid is first released from glycerolphospholipids followed by the oxidative reaction shown in Fig. 20. The ability of prostaglandins to stimulate smooth muscle contraction and regulate blood pressure was the first indication of the hormonal action of prostaglandins and related compounds. The initial and committed step in the conversion of arachidonic acid to prostaglandins is catalyzed by cyclooxygenases, also called prostaglandin enderperoxidase synthase or PGHS. Owing to the potent regulatory properties of prostaglandins, PGHS is the target for some well-known drugs. Anti-inflammatory drugs such as aspirin and ibuprofen as well the new generation of COX-2 inhibitors exhibit their effects by blocking PGHS. PGHS is a membrane-bound peroxidase, but unlike traditional

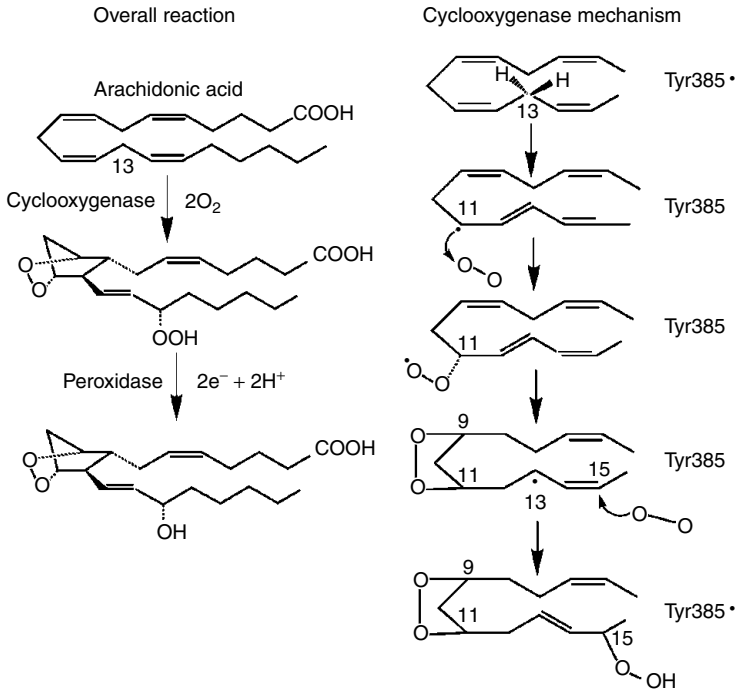

Fig. 20 The overall reaction and mechanism of cyclooxygenase. The reaction is initiated by oxidation of the substrate by a nearby tyrosine radical.

heme peroxidases, PGHS catalyzes two distinct reactions at two different sites. The first is the cyclooxygenase reaction (Fig. 20) followed by a peroxidase reaction that cleaves the O—O bond of the peroxide attached to C15 (Fig. 20). Both known isoforms, PGHS-1 and PGHS-2, are very similar and differ primarily in regulatory properties. PGHS-1 is constitutively expressed while PGHS-2 is induced.

8.2 Structure and Mechanism

The structure of PGHS-1 in a complex with arachidonic acid is shown in Fig. 21. Consisting of 576 residues PGHS-1 is much larger than the other heme peroxidases considered in this article. This increased complexity is due in part to the addition of a membrane-binding domain and the relatively large size of the substrate, and there is additional complexity in the catalytic cycle, which requires two activities. Despite these differences, the peroxidase active site is very similar to other peroxidases. Histidine serves as an axial heme ligand (Fig. 21), while in the distal pocket, His207 serves as the acid–base catalytic group required for heterolytic fission of the peroxide O—O bond. However, PGHS-1 has Gln203 in place of the distal arginine found in other peroxidases. This same type of histidine/glutamine distal site pocket is found in another mammalian peroxidase, myeloperoxidase.

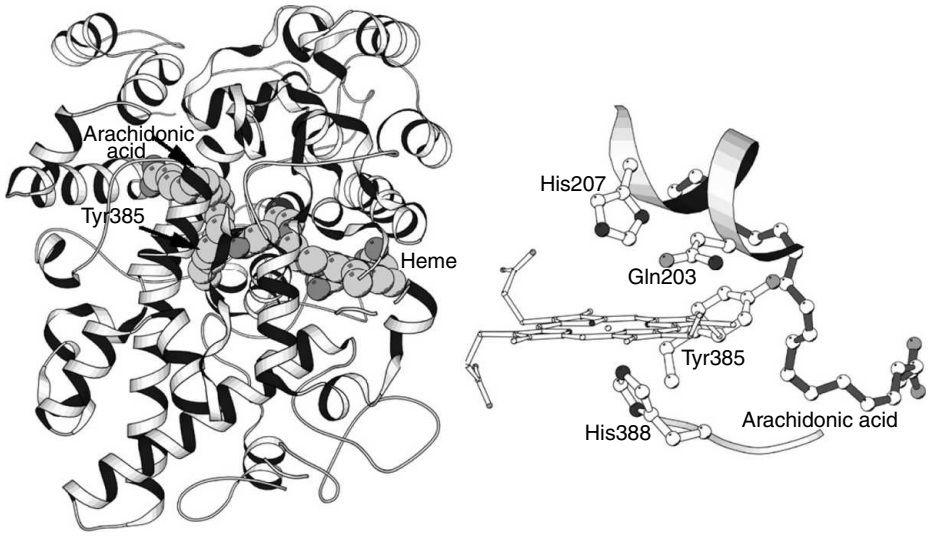

Fig. 21 The structure of PGHS-1. Although PGHS-1 is membrane bound, it is not an integral membrane protein like cytochrome *c* oxidase. Instead, PGHS contains a small membrane-binding domain, which results in most of the enzyme "floating" on the surface of the membrane. The enzyme has two active site regions. One is the heme site where peroxidase catalysis takes place. The heme active site architecture is very similar to traditional peroxidase. Note the distal His207, which operates as an acid–base catalytic group as in other peroxidases. The second site where fatty acid substrates bind is near Tyr385. The heme-site peroxidase activity results in oxidation of Tyr385 to a radical that then supports the cyclooxygenase activity as outlined in Fig. 20.

The mechanism shown in Fig. 20 requires that Tyr385 first be oxidized to a radical. This reaction is achieved *via* the traditional peroxidase mechanism.

$$Fe^{3+}P\ Tyr385 + ROOH \longrightarrow \underset{\text{Compound I}}{Fe^{4+}{-}O\ P^{\bullet}\ Tyr385} + ROH \quad (9)$$

$$Fe^{4+}{-}O\ P^{\bullet}\ Tyr385 \longrightarrow Fe^{4+}{-}O\ P^{\bullet}\ Tyr385. \quad (10)$$

$$\underset{\text{Compound II}}{Fe^{4+}{-}O\ P\ Tyr385^{\bullet}} + AA \longrightarrow Fe^{4+}{-}O\ PTyr385 + AA^{\bullet} \quad (11)$$

$$Fe^{4+}{-}O\ P\ Tyr385 + AA^{\bullet} + 2O_2 \longrightarrow^{\bullet} Fe^{4+}{-}O\ P\ Tyr385 + O_2\ AAOO^{\bullet} \quad (12)$$

$$Fe^{4+}{-}O\ P\ Tyr385 + O_2AAOO^{\bullet} \longrightarrow^{\bullet} Fe^{4+}{-}O\ P\ Tyr385^{\bullet} + O_2\ AAOOH \quad (13)$$

In Step 1, the usual Compound I is formed *via* reaction with a hydroperoxide. Tyr385 is less than 5 Å from the heme; so the oxidation of Tyr385 to a radical in Step 2 by the porphyrin radical can readily occur. As shown in Fig. 20, C13 of arachidonic acid (AA) directly contacts Tyr385, thus enabling regio- and stereoselective abstraction of the *pro*S hydrogen to give the arachidonic acid radical, AA$^{\bullet}$ After the two oxygenation reactions in Steps 4 and 5, the AA peroxy radical in Step 5 oxidizes Tyr385 to regenerate the Try385 radical. Details of the cyclooxygenase reaction in Steps 4 and 5 are outlined in Fig. 20. Reduction of O_2AAOOH to O_2AAOH proceeds *via* the traditional peroxidase mechanism to give Compound I.

9 Hydroxylamine Oxidoreductase (HAO)

HAO catalyzes the four-electron oxidation of hydroxylamine to nitrite

$$NH_2OH + H_2O \longrightarrow NO_2^- + 4e^- + 5H^+ \quad (14)$$

The electron acceptor from HAO is thought to be a *c*–type cytochrome. HAO is found primarily in microorganisms that oxidize ammonia. Little is known about the details of the HAO mechanism, but it is included in this article as an example of the fascinating complexity of some heme enzymes. The HAO monomer consists of 570 residues with a remarkable eight-heme-per-monomer structure (Fig. 22). Since functional HAO is a homo-trimer, the active enzyme contains a total of 24 hemes. One of the hemes exhibits unusual spectroscopic properties with an absorption maximum near 463 nm. The so-called P460 heme is covalently cross-linked to a tyrosine residue from a neighboring subunit. In addition, the P460 heme is also thought to be the site of substrate oxidation. The P460 heme site does share some properties with other heme enzymes. One axial ligand is histidine, while the remaining coordination position is free to interact with substrates. The P460 distal pocket contains a histidine residue that could serve the same acid–base catalytic function found in peroxidases. The remaining seven hemes most likely function to transfer electrons from the P460 site. The requirement for so many hemes may be based on the chemical requirements of converting hydroxylamine to nitrite. This is a two-step process:

$$NH_2OH \longrightarrow HNO + 2H^+ + 2e^- \text{ dehydrogenation} \quad (15)$$

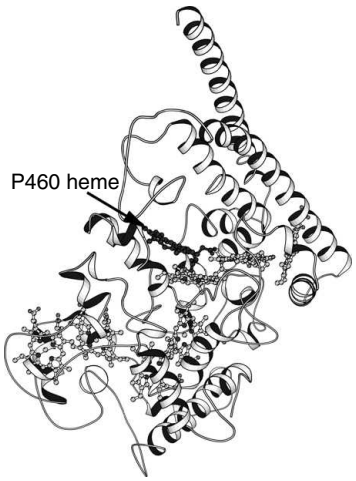

Fig. 22 The structure hydroxylamine oxidoreductase or HAO. Although HAO functions as a trimer, only the monomer is shown. Highlighted is one of the eight hemes, P460, which is the site of substrate oxidation.

$$HNO + H_2O \longrightarrow HNO_2 + 2H^+ + 2e^- \text{ oxygenation.} \quad (16)$$

HNO remains bound as an enzyme intermediate. If continuous electron flow is not maintained, the HAO generates N_2O rather than NO_2^-. Thus, two electrons must be removed, and since hemes are only one-electron carriers, it appears that the additional hemes are required to ensure the off-loading of electrons such that the HNO intermediate does not short-circuit to generate other products like N_2O or NO.

Keywords

Allosteric Protein
A protein whose active site reactivity can be altered by the binding of a ligand (the allosteric effector) at a nonoverlapping site.

Blood Substitutes
Any material (e.g. human plasma, solutions of substances such as serum albumin or dextrans) used for transfusion, as a part of treatment of hemorrhage and/or circulatory shock. Since many of these agents provide only oxygen transport and volume replacement (e.g. those based on chemically modified or genetically engineered hemoglobins), they are more correctly termed (hemoglobin-based) *oxygen carriers*. On the other hand, plasma expander is a synonym used for solutions aimed exclusively at the prevention of hypovolemic (low blood volume) shock.

Bohr Effect
The influence of pH on the oxygen affinity of hemoglobin.

Cooperativity
Any process in which the initial event (e.g. the binding of one ligand, such as O_2, to the heme iron) acts to facilitate subsequent similar events (e.g. the binding of other identical ligands) at other sites of the same polymeric protein (e.g. one tetrameric hemoglobin molecule). Cooperative processes are initially phenomenological, that is, they usually begin with the observation of sigmoid (S-shaped) curves (quite different from the rectangular hyperbola, observed in the combination of O_2 with myoglobin) obtained in the plot of ligand-saturation fraction versus ligand concentration, and later develop into a mechanistic explanation.

Geminate Recombination
The rebinding of a ligand molecule to its original site (the heme iron) after photolysis and before escaping to the solvent to mingle with other ligand molecules. The kinetics of this reaction, which typically is a picosecond to nanosecond process, is independent of bulk ligand concentration.

Kinetics and Mechanism
The study of reaction rates (called *chemical kinetics*) is concerned not only with the speed of conversion of the reactants to products but also with the sequence of physical and chemical events (whose series is called the *reaction mechanism*) by which this conversion occurs. Thus, by noting how the rate of a reaction is affected by changing experimental conditions, the chronology of discrete steps within the overall process can be determined, and details of what is happening at the molecular level in each step can sometimes be learned.

Molecular Diseases
A sickness in which the clinical manifestations arise from alterations in the structure and function of some specific biomolecule (such as an enzyme).

Molecular Evolution
The process of cumulative changes in the structure of a protein (e.g. a hemoglobin subunit) because of the stochastic element of random mutagenesis. It is generally accepted that nature evolves protein for novel function by redesigning existing protein frameworks. Only major changes in the sequence of existing genes (such as insertions, tandem duplication, and circular permutations) provide opportunities for activating latent functionalities or for producing new functions.

Hemoglobin (Hb) is the generic name for a vital protein, basic to oxygen (O_2) metabolism of all vertebrates, some invertebrates, and plants that perform nitrogen fixation. The only vertebrates that survive without Hb in their blood are antarctic fishes (such as *Chaenocephalus aceratus Lonnberg*) that bear the Hb genes but do not express the proteins. Structural and functional properties of Hb vary widely in the different species, according to physiological requirements. The multifaceted behavior of Hb has challenged the interest of many scientists with different backgrounds (biochemists, physiologists, geneticists, and biophysicists), who have investigated this protein from extremely diverse points of view (from the quantum chemistry of the heme iron to the unloading of O_2 into the swim bladder of fish, thus regulating the creature's buoyancy). Increasing concern over viral contamination of blood is spurring the development of a blood substitute; solutions of chemically modified hemoglobin represent one option.

Moreover, Hb exhibits biochemical and biophysical phenomena similar to those of many multisubunit enzymes in their interactions with substrates and cofactors. Hb, therefore, has been the prototype used to do such fundamental work in

biochemistry as determining the mechanisms by which different parts of proteins communicate (i.e. the structural basis of cooperativity and allostery). It is not, therefore, surprising that tetrameric Hb has been called the *hydrogen molecule of biochemistry* because understanding its functions is so basic to protein chemistry at large; the hydrogen atom has been considered as myoglobin (Mb), the monomeric hemoprotein contained in red muscles.

1 General Aspects

Hemoglobin is a protein able to undergo a reversible reaction with O_2 by virtue of containing heme (Fe-protoporphyrin IX) as the prosthetic group. Classically, hemoproteins present in the blood or the hemolymph of vertebrates and invertebrates are named *hemoglobin* (Hbs), while those present in the striated or smooth muscles of all animals are called *myoglobin* (Mbs). However, Hbs dissolved in the blood of invertebrates are often called *erythrocruorins*. Very recently, simple hemoproteins similar to Hbs but different from Mbs have been discovered in tissues of humans, such as liver (named *cytoglobin*) and brain (named *neuroglobin*). Proteins having characteristics corresponding to the foregoing definition are also found in tissues of invertebrates other than blood and muscle (e.g. in the cells of the tracheal wall in *Gastrophylus* larvae or in the nerve cells of marine mollusks), in plants (e.g. lupin and soybean), and in single-cell organisms (e.g. protozoa, fungi, and bacteria): in all these cases, the term Hb has been adopted. A number of microorganisms (such as *Mycobacterium tuberculosis*) were recently shown to express Hbs, which are important components of pathogenicity. Examination of their three-dimensional structure clearly shows that these new hemoproteins belong to the extended globin superfamily, in spite of the fact that their polypeptidic chain is approximately 30% shorter than classical Hbs; this is why they have been designated *truncated Hbs*. On the other hand, the O_2 carrier present in the blood of several polychaete worms is named *chlorocruorin* since its prosthetic group is a chloroporphyrin, characterized by a formyl group substituted for the vinyl group in position 2 of the protoporphyrin IX.

In this article, attention is mainly focused on human Hb, the intraerythrocyte protein involved not only in the transport of O_2 from lungs to tissues but also in the reverse transport of carbon dioxide. Hb concentration in normal human erythrocytes is extremely high (340 g dm^{-3}) and corresponds to a 5.2 mM solution, taking a molecular mass of 65 000 g mol^{-1}. One erythrocyte contains approximately 300 million Hb tetramers. Even though the erythrocyte Hb molecules (which are spheroids of dimension $6.4 \times 5.5 \times 5$ nm) are on average only 1 nm apart, they can rotate and flow past one another without hindrance. All general ideas that originated from studies on human Hb have been successfully transferred to other vertebrate and invertebrate Hbs, and in general, to more complex respiratory proteins, which are sometimes very large and extracellular.

2 Structural Features and Basic Terminology

Hemoglobin consists of four polypeptide chains (globins). These apoproteins carry as a prosthetic group the heme, an Fe(II) complex of protoporphyrin IX (synthesized in the bone marrow from glycine and acetate). In the free heme, Fe(II) is rapidly oxidized to Fe(III) by O_2 and water, whereas in Hb, Fe(II) combines reversibly with O_2 and remains in the ferrous state in both the oxygenated and deoxygenated derivatives. Reversibility in binding with O_2 is achieved in Hb by the folding of the polypeptide chain around the heme group, which is enclosed in a hydrophobic pocket. When O_2 is bound at the Fe(II) (in a 1 : 1 stoichiometry), an electron rearrangement occurs, with the Fe(II) changing from high spin to low spin and the adduct acquiring the $Fe(III)O_2^-$ character.

Hemoglobin subunits are identical in pairs: each polypeptide chain of the two subunits designated α^1 and α^2 (where indices are used to denote relative location in the tetramer) has 141 amino acid residues; each of the β^1 and β^2 subunits has 146 amino acid residues. The tetrameric molecule of adult normal Hb is usually indicated as $\alpha_2\beta_2$. The α- and β-subunits have different amino acid sequences (see Table 1), but they fold up spontaneously into a similar three-dimensional structure (see Fig. 1), the so-called *globin fold*. The α- and β subunits, respectively, are made

up of seven and eight α-helical segments, interrupted by nonhelical sections. The helices are named from A to H, and the nonhelical segments lying in between are lettered AB, BC, and so on; the nonhelical portions at the subunit ends are named NA (at the amino terminus) and HC (at the carboxyl terminus). Residues within each segment (helical as well as nonhelical) are numbered from the amino end (e.g. A1–A16, EF1–EF8, etc.). Therefore, each amino acid residue (usually represented with the three-letter code) is uniquely identified by its topology, its position in the

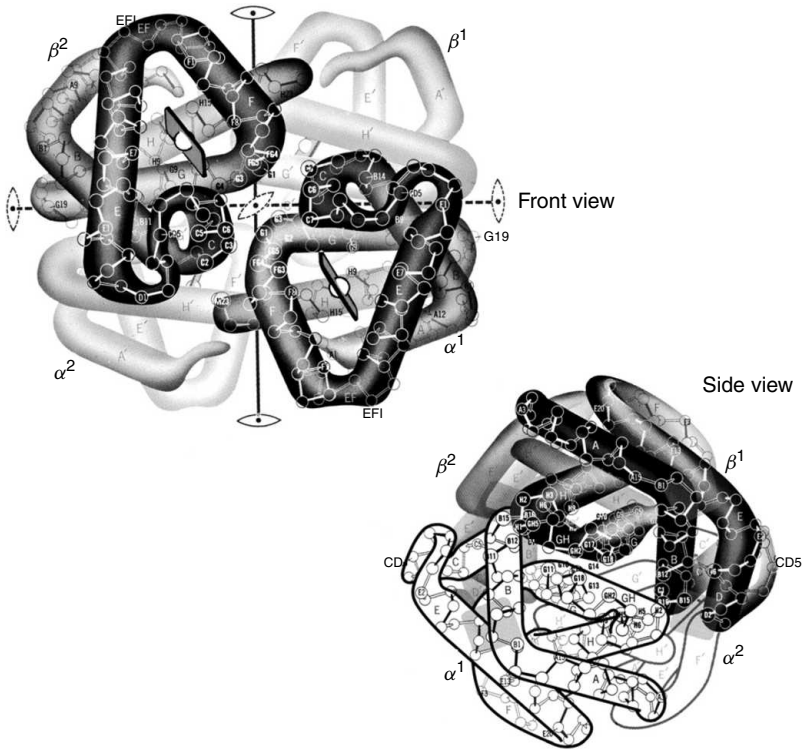

Fig. 1 Overview of ferric Hb, which is similar to the oxygenated derivative (HbO_2). Only the α-carbons of the main chains are shown. Those residues whose side chains are involved in contacts between subunits are circled and given boldface numbers. There are two kinds of unlike subunit contact: $\alpha^1\beta^1$ (or $\alpha^2\beta^2$) and $\alpha^1\beta^2$ (or $\alpha^2\beta^1$), the first interface being more extensive than the second (see also Table 2); the $\alpha^1\beta^1$ contact involves the B, C, and H helices and the GH corner, whereas the $\alpha^1\beta^2$ contact concerns mainly helices C and G and the FG corner. [Reproduced with permission from Irving Geis and R. E. Dickerson (1983) *Hemoglobin: Structure, Function, Evolution and Pathology*, Benjamin/Cummings, Menlo Park, CA.]

sequence (in parentheses), and the corresponding subunit [e.g. PheCD1(42)β].

The heme is bound to the globin by a number of weak hydrophobic interactions and by the mainly covalent bond between Fe(II) and the imidazole-N_ε of histidine F8, known as *proximal*.

In the β subunits, such a residue is followed by a reactive cysteine [CysF9(93)β], which faces the surface of the molecule: most, but not all, globins also have a histidine (HisE7, known as *distal*) on the O_2-combining side of the heme. This residue, however, is too far (>0.4 nm) from the iron to be expected to directly coordinate with the metal, even though under certain conditions, it does bind with the metal (see Sect. 4.2); usually, the N_ε atom of HisE7 makes a hydrogen bond with bound O_2 (see Fig. 2). The packing of subunits into the Hb tetramer is such that there are close interlocking connections of side groups between unlike subunits (i.e.

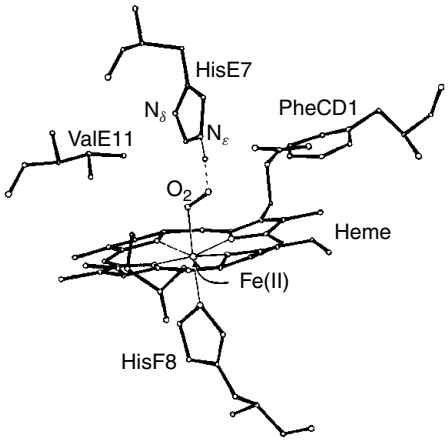

Fig. 2 Schematic representation of the heme pocket. Phenylalanine CD1 and the proximal histidine F8 are present in all hemoglobins. In vertebrates, valine E11 and the distal histidine E7 are involved in the reversible O_2 binding to the heme Fe(II). Note the hydrogen bond between the N_ε of the distal HisE7 and the bound O_2 molecule. HisE7 has a pK_a of about 5.5. Neutron diffraction has shown that in MbO_2, this amino acid is protonated only on N_ε, whereas in the carbon monoxy derivative, protonation occurs only on N_δ, which faces the bulk water.

Tab. 2 Surface area (nm^2) buried between contact interfaces in deoxy and oxy human hemoglobin.

Nature of surface area	*Deoxy Hb*	*Oxy Hb*
Buried in contact		
$\alpha^1\beta^1$ or $\alpha^2\beta^2$	18.76	20.48

Accessible to solvent	72.55	80.32

α and β) but little contact between those that are alike (see Table 2).

3 Hemoglobin Components in Erythrocytes

Besides $\alpha_2\beta_2$ (also called HbA or HbA_0), human erythrocytes contain other Hb components, some as products of additional globin genes and others as posttranslational modifications of all these components. Among the hemoproteins belonging to the first group are HbA_2 and HbF (or fetal Hb), constituted from normal α-chains and combined with subunits whose structure differs significantly from that of normal β-chains; these non-α subunits are designated δ-chains (HbA_2 or $\alpha_2\delta_2$) and γ-chains (HbF or $\alpha_2\gamma_2$). Humans have also two embryonic Hbs using ζ- (α-like) and ε- (β-like) subunits: Hb Gower-1 of composition $\zeta_2\varepsilon_2$, Hb Gower-2 or $\alpha_2\varepsilon_2$, and Hb Portland or $\zeta_2\gamma_2$. Amino acid sequences of human chains are reported in Table 1.

Many small molecules (e.g. hexoses, cyanate ions derived from urea, and penicillin) are capable of forming covalent adducts with Hb and may reflect metabolic perturbation. Of significance for their clinical implications in diabetes are glycated Hbs (called Hb A_{Ia1}, A_{Ia2}, A_{Ib}, and A_{Ic}, according to their order of chromatographic elution) in which the amino terminus of the β-chains is bound to a molecule of glucose, glucose 6-phosphate, or fructose 1,6-bisphosphate; glucose can also form a ketoamine linkage with the amino-terminal group of α-chains as well as the ε-amino group of several lysyl residues of both α- and β-subunits. HbA_{Ic} is the most abundant minor (posttranslationally modified) Hb component in human erythrocytes, reaching about 4% of the total.

4
Derivatives with Heme Ligands

4.1
Ferrous Derivatives

The form of ferrous Hb with no ligand attached to the heme iron has been named unligated Hb (or deoxy Hb). It may be prepared by removal of the heme ligand (such as O_2, CO, NO, alkylisocyanides, and nitroso aromatic compounds, with NO being the strongest and bulky alkylisocyanides being the weakest ligand) from the corresponding ferrous ligated form. Usually, the starting derivative is oxygenated Hb (oxy Hb or HbO_2) and deoxygenation is achieved when such a derivative is exposed to vacuum or is equilibrated with an inert gas (e.g. N_2, Ar) or by addition of sodium dithionite ($Na_2S_2O_4$), which removes O_2 from solution. Deoxy Hb may also be prepared from the ferric derivatives by reduction of the Fe(III) by borohydride, dithionite, or ascorbate.

4.2
Ferric Derivatives

In the presence of O_2, the Fe(II) is subject to slow spontaneous oxidation, yielding ferric Hb or met Hb (which cannot combine with O_2). In blood, the rate of autoxidation is about 3% per day, but the oxidized iron-porphyrin is reduced to its active form by reductase systems. *In vitro* ferrous derivatives (such as oxy and deoxy Hb) are oxidized rapidly by ferricyanide or by nitrite. The water molecule bound to the Fe(III) in met Hb can be replaced by F^-, OCN^-, SCN^-, N_3^-, imidazole, or CN^-, where F^- is the weakest and CN^- the strongest ligand.

An endogenous ligand, such as the imidazole of distal HisE7, may also bind to Fe(III). This is a state that is either actually part of the distribution of substates populated in native Hb (named *bis-histidine complex* since the fifth and sixth axial positions of the Hb–Fe(III) are coordinated by proximal and distal histidines respectively), or may result from a large alteration of the geometry within the heme pocket; in this case, the low-spin derivative is called a *hemichrome*, a term connoting a denatured state. A more pronounced denaturation of the protein may cause the formation of other hemichromes; in one of these, one ligand of the Fe(III) is the sulfur of CysF9(93)β. Addition of dithionite to the hemichromes results in the reduction of heme Fe(III) to Fe(II), with the production of low-spin compounds called *hemochromes*.

5
The Reaction with Heme Ligands

The reaction of Hb with O_2 or other ligands of the ferrous heme is associated with large modifications of the spectral (see Fig. 3) and magnetochemical properties, which change in proportion with the amount of ligand bound.

5.1
Functional Properties at Equilibrium

The fundamental representation of the reversible combination of Hb with O_2 is the ligand-binding curve wherein the fraction of O_2-bearing heme groups (Y) is measured as a function of the O_2 partial pressure (p). The sigmoid shape of the curve is in marked contrast to the rectangular hyperbola found for the isolated α- or β-subunits (and also for

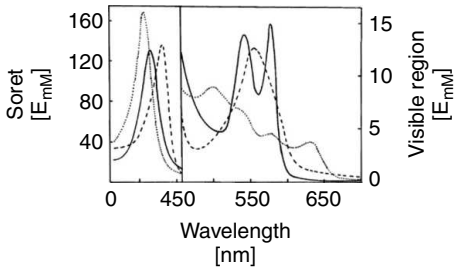

Fig. 3 Optical absorption spectra of deoxy (dashes), oxy (solid curves), and met (dots) hemoglobins in the visible and near-ultraviolet (the so-called Soret band) regions at pH 7.4: E_{mM}, millimolar extinction coefficient in heme (i.e. referred to an equivalent molecular mass of 16 250 g mol^{-1}).

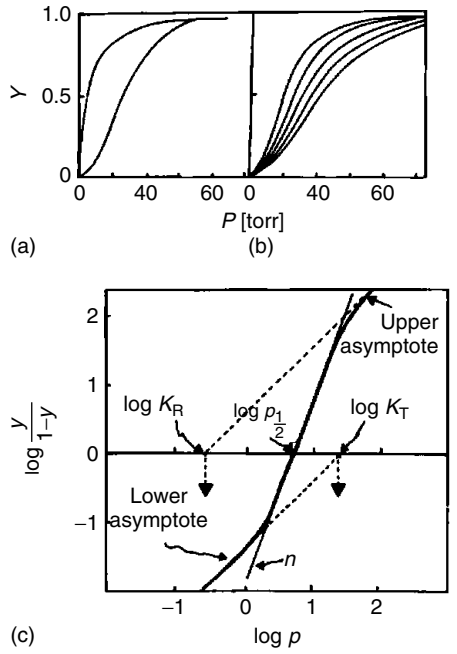

Fig. 4 Two ways of plotting the O_2 equilibrium curves of hemoglobin: (a) and (b) fractional saturation with O_2 (Y), reported as a function of O_2 partial pressure (p); (c) the Hill plot – see Eq. (5). (a) The typical shape of the O_2 equilibrium curve for Hb is sigmoid (right), while the curve for isolated β-subunits is hyperbolic (left). Both proteins are tetrameric ($\alpha_2\beta_2$ and β_4). In the case of the β-subunits, the four O_2-binding sites are equivalent and independent; on the other hand, the shape of the Hb oxygenation curve implies that the affinity of the free sites depends on the fraction of hemes already bound to O_2; (b) O_2-binding curves for Hb at various pH values (i.e. the Bohr effect): left to right, pH 7.6, 7.4, 7.2, 7.0, and 6.8; (c) the Hill plot for Hb oxygenation begins and ends with straight lines, called *asymptotes*, with a positive slope of unity ($n = 1$). The intercepts of these asymptotes, with the line parallel to the abscissa when $\log[Y/(1 - Y)] = 0$ (i.e. when oxy and deoxy Hb are equal in concentration) give the values of the O_2 equilibrium constants for the T state (K_T) and the R state (K_R). Often the asymptotes cannot be determined accurately; in such cases, the oxygenation process is described in terms of the maximum slope of the curve n (taken as a measure of the degree of cooperativity) and the overall O_2 affinity in logarithmic terms (i.e. $\log p_{1/2}$), which corresponds to the value of $\log p$ when $\log[Y/(1 - Y)] = 0$ (see Table 3).

Mb, see Fig. 4a). The sigmoidal curve reflects a phenomenon called *cooperativity*, a complicated process whereby initial O_2 binding favors more binding (as would occur in the lungs), or, from the opposite perspective, some O_2 release favors more release (as would occur in the peripheral tissues). Cooperativity characterizes all vertebrate Hbs, the only exception so far being the Hbs from *Sphenodon punctatus*, a reptilian relict from the Triassic period.

A useful way of analyzing the experimental data is based on the following scheme:

$$\mathrm{Hb} + n\mathrm{O_2} \rightleftharpoons \mathrm{Hb(O_2)}_n \qquad (1)$$

Assuming that the ratio of activities of Hb and $Hb(O_2)_n$ is given by their concentration ratio, the association equilibrium constant, K, can be written as follows:

$$K = \frac{[Hb(O_2)_n]}{[Hb]p^n} \qquad (2)$$

where the activity of O_2 is expressed in terms of its partial pressure p. The average fraction of hemes oxygenated is

$$Y = \frac{[Hb(O_2)_n]}{[Hb] + [Hb(O_2)_n]} \qquad (3)$$

Therefore, replacing $[Hb(O_2)_n]$ by Eq. (2), Eq. (3) gives

$$\frac{Y}{1-Y} = Kp^n \qquad (4)$$

or in logarithmic terms (the so-called *Hill equation*; see Fig. 4c),

$$\log \frac{Y}{1-Y} = \log K + n \log p \qquad (5)$$

Equation (5) has no direct physical meaning but, with a suitable choice of K and n, it is able to empirically fit the experimental results with only two parameters: (1) $p_{1/2}$, that is, the value of O_2 pressure required to yield half saturation of hemes (p value at $Y = 0.5$), which indicates the overall affinity of Hb for O_2 (the higher the affinity, the lower the $p_{1/2}$); and (2) n, the slope in the Hill plot (see Fig. 4c), which is related to the shape of ligand-binding curve and therefore to cooperativity (the higher its value above 1, the higher the cooperativity). A value of n equal to 1 (as occurring in tetrameric β-subunits) corresponds to a hyperbolic binding curve, indicating equivalence of hemes and absence of functional interactions. Observation of n less than 1 does not necessarily imply negative cooperativity (i.e. that binding of a ligand diminishes the affinity for subsequent binding) in that it can also arise from various kinds of heterogeneity: intramolecular (e.g. large difference in affinity for O_2, between α- and β-subunits in the tetramer) or intermolecular (e.g. mixture of various Hb species or conformations not at equilibrium). The O_2 affinity of Hb is lowered by H^+, Cl^-, CO_2, and 2,3-D-bisphosphoglycerate (BPG), all known as *heterotropic ligands*. In particular, the O_2-binding modulation by H^+ is known as the *Bohr effect* and reflects the release of protons upon Hb oxygenation at physiological pH (the alkaline Bohr effect), whereas protons are taken up upon oxygenation at pH values below ~6 (the acid or reverse Bohr effect). An unusually large Bohr effect, typical of some Hbs from many teleost fishes, is called the *Root effect*. By increasing the concentration of any one of the heterotropic ligands, the O_2 equilibrium curve is shifted to the right (see Fig. 4b) – that is, toward lower affinity – thus facilitating O_2 release. Table 3 reports the O_2-binding parameters at equilibrium of human Hb under different solvent conditions.

From a phenomenological viewpoint, mammalian Hbs can broadly be divided into two groups: those with an intrinsically high O_2 affinity, which is lowered in the erythrocytes by BPG, and those with an intrinsically low O_2 affinity, which is lowered little, or not at all, by BPG. Rodents, pigs, dogs, camels, horses, marsupials, and most primates belong to the first category; cats, sheep, goats, deer, cows, and one primate, the lemur, belong to the second. Typically, Hbs with high intrinsic O_2 affinity have $p_{1/2}$ values between 4 and 6 torr, while those with low affinity have $p_{1/2}$ values between 10 and 20 torr (measured at 20 to 25 °C in 0.05 M bis-Tris, with Cl^- concentration of 0.1 M, pH 6.5 to 7.5 as shown in Table 3).

Tab. 3 Values of parameters describing the functional properties of human hemoglobin in 0.05 M Tris, pH 7.4; Cl^- concentration 0.10 M, and 20 °C.

5.2 Kinetic Aspects

Hemoglobin kinetics with ferrous heme ligands approximates second-order behavior in the combination direction and first-order behavior in the dissociation direction. Among the gaseous ligands that bind to the ferrous derivatives, at neutral pH and room temperature, NO binds fastest, O_2 not quite as fast, and CO significantly more slowly. The dissociation reactions follow a different order (see Table 3). When the rate constants of binding (k') or dissociation (k) of the first and fourth gaseous ligands are compared, the kinetic manifestation of cooperativity is observed (see Table 3). In this connection, it has been shown that cooperative binding in kinetic terms results from a significant increase in the association rate constants for CO and a decrease in the dissociation rates for O_2 and NO; accordingly, the transition state, as compared to reactants and products along the reaction path to heme, is expected to be reactant-like for O_2 and NO, and product-like for CO.

Since light breaks the bond between heme–Fe(II) and all heme ligands, the kinetic behavior of rebinding can be investigated after rapid photodissociation by illuminating with a laser pulse. The relaxation kinetics over all chemically meaningful timescales (from picosecond to second) demonstrates the existence of different rate-limiting steps for the various heme ligands and, therefore, the existence of intermediates in the reaction pathway. A four-state scheme is required:

$$\begin{array}{ccccc} \text{HbX} & & \text{P} & & \text{M} \\ \text{ligand} & \rightleftharpoons & \text{heme} & \rightleftharpoons & \text{protein} \\ \text{bound} & & \text{pocket} & & \text{matrix} \\ & \rightleftharpoons & \text{Hb} + \text{X} & & \\ & & \text{bulk} & & \end{array} \qquad (6)$$

where: HbX represents the bound state, Hb + X is an unligated molecule (i.e. the two entirely separated free species, Hb and X), P and M are intermediate states in which the heme Fe has no sixth ligand, but X remains trapped either in the heme pocket P or in the protein matrix M. From the latter states, the ligand may either rebind (to yield HbX) in a *geminate process* or escape to the solvent (to yield Hb + X).

The structural features of states P and M have been investigated by X-ray diffraction in single crystals of carbonylated myoglobin (MbCO). The short-lived photolyzed state was shown to be structurally complex in so far as the photolyzed CO migrates inside the protein matrix while in state M, before escaping into the bulk or eventually recombining in what has been called *geminate rebinding*. Moreover, room-temperature, time-resolved Laue crystallography has pointed out that during its pathway inside the protein matrix, CO momentarily occupies small internal cavities, previously shown to be able to bind one atom of xenon.

If the data are forced into the four-step scheme, as in Eq. (6), the biochemical system (e.g. HbCO) starts in the potential-well HbX, in which the ligand (e.g. CO) is bound to the heme Fe. When the laser flash breaks the Fe–ligand bond, the system rapidly moves (relaxation time about 3 ps) to well P where the ligand molecule is in the heme pocket. At this point, the three gaseous ligands (O_2, CO, NO) behave differently. On a picosecond to nanosecond timescale, all ligands except CO show a substantial fraction of geminate rebinding; thus, at approximately 100 ps, HbX is the predominant form after photolysis of NO, while M predominates after photolysis of CO, and O_2 is more evenly distributed between HbX and M. Further evolution of species M is orders of magnitude slower (nanoseconds). Although the overall rates are much the same for O_2, CO, and NO, the amplitude of this second phase is different for the three ligands, the value being smallest for NO (since for this ligand, the picosecond rebinding process is dominant and, accordingly, little ligand is left to react in the nanosecond geminate process). Without discussing the chemistry yielding the difference between NO and CO, we note that the rate-limiting step in bimolecular NO binding is the diffusion of ligand into and within the protein since reactivity with the heme is so high that almost every NO molecule that approaches will bind; on the other hand, assuming a similar rate of diffusion, only a small fraction of the photodissociated CO rebinds in a geminate mode.

6 Mechanisms of Cooperative Binding and Allostery

Cooperative binding of O_2 by Hb is the classical example of what is referred to as an *allosteric phenomenon*, which defines the concept that the binding of a ligand at one site on a macromolecule affects the binding of a second ligand at another site via a conformational change or an allosteric transition. In allosteric binding, therefore, the uptake of one ligand (e.g. one O_2) by an oligomeric protein (e.g. tetrameric Hb) influences the ligand affinities of the remaining unfilled binding sites; in human Hb, the fourth O_2 molecule binds with a 200-fold higher affinity than the first one. Likewise, binding of oxygen at the heme is affected by the association of other ligands (e.g. H^+ or BPG) at different nonheme sites on the protein.

The detailed structural bases of cooperativity continue to elicit contrasting views. A number of models have been proposed that in various ways hybridize the two classical theories developed during the 1960s by J. Monod, J. Wyman, and J. P. Changeux (often referred to as the *MWC model*) and by D. E. Koshland, G. Nemethy, and D. Filmer (often referred to as the *KNF model*). Actually, the MWC and KNF models are the limiting cases of a more general

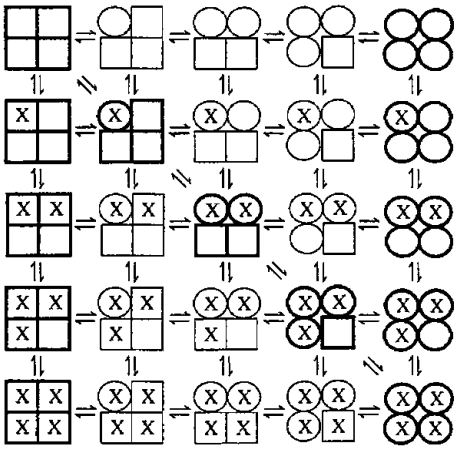

Fig. 5 General representation of ligand (X) binding and ligand-linked conformational changes, illustrating the contrasting ways of generating cooperativity according to the sequential or KNF model (indicated by the diagonal in boldface) and the concerted or MWC model (represented by the equilibria between the two extreme columns, all intermediates being absent or negligible or undetectable). Each subunit within the tetramer can have only two distinct tertiary conformations, one (circle) with high affinity for heme ligand or R state and the other (square) with low affinity or T state. In the sequential model, heme–ligand binding induces an isomerization in each ligated subunit, which assumes the high-affinity conformation; the unligated subunits retain their low-affinity structure, even though the contacts with the ligated neighbor(s) are altered, thereby increasing the tendency to switch to the high-affinity state. An important property of the sequential model is that the extent of binding and structural changes determined at different ligand concentrations must be identical. In the concerted model, the tetramer is postulated to exist in only two quaternary states (R and T) in which all four protomers are in either one of two conformations (squares or circles). The quaternary states are in equilibrium with each other at every degree of saturation: the fully ligated tetramer is predominantly in the R state, whereas the T state is favored in the fully unligated species. The conformational transition of the subunits (between square and circle) is concerted, involving all protomers within the tetramer, with the result that the molecule conserves structural symmetry. This corresponds to an extreme case of cooperativity among the protomers, characterized by a virtual absence of the hybrid states (i.e. coexistence of circles and squares in one tetramer), which, on the contrary, are present in the sequential model. The sequential model can account for both positive and negative cooperativity, whereas the concerted model can accommodate only positive cooperativity.

scheme that can be depicted as a square array (Fig. 5) such that the number of allosteric conformers (in a row) equals the number of binding species in a given column, including the unligated or reference species. The entire system of chemical species (macromolecule and small ligand, X) is considered to be in equilibrium. The reactions within the array are described by appropriate mass action laws and involve the addition of iX ligands and a change of the cth molecular conformation, as follows:

$$\mathrm{Hb}_{00} + i\mathrm{X} \rightarrow \mathrm{Hb}_c\mathrm{X}_i \qquad (7)$$

For tetrameric human Hb (and, in general, for all vertebrate Hbs), each conformation can bind a maximum number of four X ligands, and, accordingly, there are $4 + 1$ conformations in the square array (i.e. 4 ligated and 1 unligated). The MWC two-state model postulates that the two extreme allosteric states (first and fifth columns of Fig. 5) are the dominant ones; the KNF model envisages the species along one of the diagonals to be preferentially populated (see Fig. 5). Since high cooperativity is always associated with reduction of the population of the intermediate species (partially oxygenated Hb intermediates never exceed a few percent of total Hb), these two alternative mechanisms are, to all intents and purposes, indistinguishable by analysis of O_2 binding data, which, in fact, are often described by Eq. (5), the empirical Hill equation.

6.1 Concerted Model of Allostery

Among the various approaches emphasizing the role of subunit–subunit interactions, the concerted (or MWC) model has a very simple algebraic description. Its basic idea is that the intrinsic O_2 affinity at the heme is controlled by the quaternary structure of the protein rather than by the number of ligand molecules already bound to the tetramer. This model assumes that there are only two different quaternary structures: one with fewer and weaker interactions among the subunits (fully ligated Hb or relaxed R) and the other with more and stronger bonds between the subunits (deoxy Hb or tense T). In the R or high-affinity state, Hb displays the ability to bind O_2 tightly; this functional property is damped but not abolished in the T or low-affinity state. On the other hand, the T state interacts more strongly than the R state with heterotropic ligands (H^+, Cl^-, BPG, and CO_2). The transition from T to R is an all-or-none process: the symmetry of the molecule is conserved (i.e. hybrid RT states cannot exist) and the O_2 affinity of all subunits in a tetramer would be either equally low or equally high. Oxygenation of the subunits within each quaternary state is associated with small local structural changes such that the T state, with one O_2 molecule bound, and the R state, with three O_2 molecules bound, will have conformations that are locally different from those of the unligated T and fully ligated R respectively. The assumption of the concerted model in its original formulation is that these local structural differences are not transmitted to neighboring subunits and thus do not alter their O_2 affinity; rather, they affect the relative stability of the R and T quaternary states. Therefore, although binding to the four hemes in each of the T and R states is itself noncooperative, the shift in the T ↔ R equilibrium gives rise to a sigmoid binding curve.

The MWC model allows one to describe the ligand binding by Hb at equilibrium, with only three independent parameters: the two microscopic dissociation constants of O_2, with the protein in low-affinity (K_T) and high-affinity (K_R) states, often reported in terms of a ratio $c(= K_T/K_R)$, and the concentration ratio of the two quaternary states in the absence of ligand $L_0 = [T]_0/[R]_0$. The total free energy of cooperativity, δG^0, can be calculated from the binding of the last and first ligand molecules, which is approximately equal to $\delta G^0 = 2.303\ RT \log(K_R/K_T)$ (i.e. the difference in free energy of binding O_2 to the R state and the T state).

Values of parameters illustrating the interpretation of the cooperative effects in terms of the MWC model are reported in Table 3. The effect of heterotropic ligands (H^+, Cl^-, BPG, and CO_2) is also described in terms of the concerted allosteric model as follows: addition of BPG (which binds to the Hb tetramer in a 1 : 1 ratio) shifts the equilibrium in favor of the T structure, with an increase of L_0; the same effect is obtained by lowering pH.

The original MWC model assumed K_T and K_R to be intrinsic parameters independent of heterotropic ligands. However, detailed functional O_2-binding data, coupled with the structural knowledge gained from X-ray crystallography and spectroscopic studies indicate that, in human HbA_0, K_T varies over a wide range as a function of H^+, Cl^-, CO_2, and BPG concentration, whereas K_R is little affected by heterotropic ligands (except by protons, and only below pH 7). Thus, the original MWC model had to be modified.

In general, each quaternary state (T or R) may differ in tertiary conformation of the subunits (t or r), depending on the lower or higher intrinsic heme–ligand affinity of the chains (squares and circles in Fig. 5), and therefore, the system may be described in terms of (at least) four alternative states denoted as follows: Rr and Rt, for conformations at high and low affinity for heme ligands of the subunits within the R structure, and Tt and Tr, for low and high-affinity conformations of chains within the T structure.

6.2 Structural Changes That Accompany Oxygen Binding

The T state is assumed to have quaternary interactions between subunits typical of deoxy Hb, while the R state is believed to have those of oxy Hb (as determined by crystal X-ray diffraction data). In deoxy Hb, the Fe is displaced from the plane of the porphyrin nitrogens toward the proximal histidine by 0.06 nm. There are two reasons for this: (1) the larger radius of the Fe in its high spin state; and (2) steric repulsions between the N_ε of the proximal histidine and the porphyrin nitrogens. Moreover, the heme group is domed, that is, the Fe-bound nitrogens of the porphyrins are out of the plane of the carbon atoms of the heme (see Fig. 2), by 0.016 nm in the α-subunit and by 0.01 nm in the β-subunit. Upon single-subunit oxygenation, the Fe atom barely moves toward the porphyrin, which remains domed within the T state; this prevents the heme from adopting the optimal geometry with the bound oxygen (i.e. planar with the Fe in "the plane"), thus producing strain. Relief of strain at the active site requires the Fe to move toward the porphyrin plane, accompanied by a displacement of the proximal histidine together with the helix F and the corner FG (the so-called *allosteric core*). In particular, in both subunits, there is a shift of helix F across the heme plane by about 0.1 nm, accompanied by a rotation; the overall effect is to permit a reorientation of the proximal histidine so that the Fe can move toward the heme plane.

To understand the connection between the foregoing tertiary modifications and quaternary structural changes, the Hb tetramer can be thought of as a pair of dimers, $\alpha^1\beta^1$ and $\alpha^2\beta^2$, whose relative orientation has to alter; in fact, the contacts $\alpha^1\beta^1$ (and $\alpha^2\beta^2$) remain rigid. The tertiary changes make these dimers a misfit in the quaternary T structure, with consequent promotion of the T-to-R transition. The transition consists of a 12 to 15° rotation of the dimer $\alpha^1\beta^1$ relative to the dimer $\alpha^2\beta^2$ and a translation of one dimer relative to the other by 0.08 nm (Fig. 6). Helix C β_2, which is in contact with the corner FG α_1, forms a ball-and-socket joint around which the dimers turn, while helix C α_1 slides relative to FG β_2. Together, the two contacts form a two-way switch that ensures that the $\alpha\beta$ dimers click back and forth between the two stable quaternary positions (T and R).

All heterotropic ligands at physiological pH lower the O_2 affinity by forming additional hydrogen bonds that specifically stabilize the T structure. BPG binds in a cavity on the dyad axis of the tetramer, limited by the amino termini and helices H of the β-subunits; it forms hydrogen bonds with ValNA1(1), HisNA2(2), LysEF6(82), and HisH21(143). The functionally relevant protons (i.e. those released upon oxygen uptake and on the basis of the Bohr effect; see also Fig. 4b) are discharged in deionized solution only

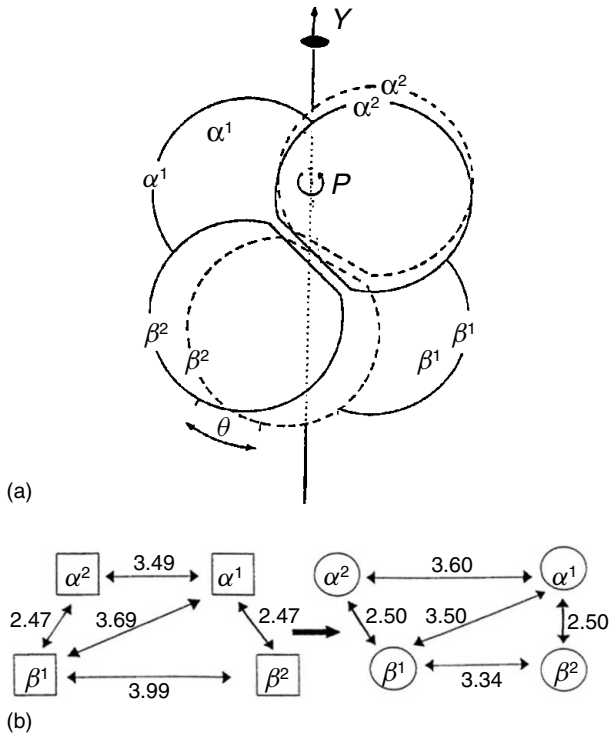

Fig. 6 Schematic diagram illustrating the change in quaternary structure (a) and in distances (nm) between heme groups (b) that accompanies ligand binding to Hb. Bold symbols refer to the deoxy derivative and light symbols to ligated Hb. Both structures have a dyad axis (*Y*) relating the $\alpha^1\beta^1$ dimer to the $\alpha^2\beta^2$ dimer, and the molecular contacts between α^1 and β^1 (as well as those between α^2 and β^2) change very little; accordingly, the positions of ligated and unligated $\alpha^1\beta^1$ dimers have been superimposed. The main differences between the two conformational states, in going from the deoxy to the ligated derivative, are (1) a rotation of about 13.5° (θ) about a pivot (*P*) of the $\alpha^2\beta^2$ dimer relative to the $\alpha^1\beta^1$ dimer so that the two β chains are about 0.6 nm further apart in the former than in the latter; and (2) a shifting of the $\alpha^2\beta^2$ dimer along the *P* axis by about 0.1 nm into the page. Major conformational change in the T-to-R transition involves the $\alpha^1\beta^2$ (and $\alpha^2\beta^1$) subunit interfaces.

from HisHC3(146)β, a residue that forms a hydrogen bond with AspFG1(94)β in the T structure. In the presence of Cl^- and/or BPG, other residues [e.g. ValNA1(1)β and LysEF6(82)β] contribute additional Bohr protons.

6.3 Ligand-binding Pathways

Hemoglobins have a binding pocket at the heme that protects Fe(II) from the solvent. This feature has biological importance

because, in water, the heme Fe(II) can oxidize into the inactive ferric state. The stability of the $Fe(II)O_2$ complex in Hb is controlled by the presence of a hydrogen bond with the distal histidine (located at E7; see Table 1), as in Fig. 2. This crucial interaction, in fact, slows the rate of O_2 dissociation from microseconds (which has been measured in sperm-whale Mb mutant with valine at E7) to many milliseconds, and simultaneously increases the O_2 affinity to physiologically meaningful values; moreover, it reduces the rate of autoxidation of the heme Fe(II), which, otherwise, would occur much too rapidly since oxidation happens in the fraction of Hb that is deoxygenated at any one moment (the larger the fraction of molecules, the faster the Hb autoxidizes).

Examination of the X-ray structures of many hemoproteins shows that the protein environment of the heme, if rigid, would prevent the entrance and the exit of even small gaseous ligands (e.g. O_2, CO). Empirical energy function calculations, based on the crystallographic coordinates, have shown that possible pathways in the neighborhood of the heme pocket would have barriers of the order of 400 kJ mol^{-1} in a rigid protein; such energy barriers would lead to escape times (of ligand from the heme pocket) of the order of 10^{60} seconds at room temperature, infinitely long on any timescale. Thus, protein fluctuations are required for physiological function. The dynamics of the heme pocket residues are revealed by the results of NMR and other studies, showing that PheCD1(43) and PheCD4(46), which wedge the prosthetic group into its pocket and are packed tightly between the heme and the distal helix E, flip over at rates faster than 10^4 s^{-1}; this is possible only if the entire heme pocket breathes fast.

Dihedral rotations of key side chains, explored by molecular dynamics, indicate that energy barriers ($\approx$40 kJ mol^{-1}) would be present in a fluctuating protein; these barriers are compatible with those estimated from rebinding studies for HbCO after photolysis. This dilemma has been addressed by (1) examining X-ray structures with small (e.g. CO) and bulky (e.g. alkylisocyanides) ligands bound to the heme Fe; (2) temperature-dependent X-ray diffraction; (3) molecular dynamics simulation; (4) time-resolved crystallographic experiment on photolyzed Mb crystals; and (5)site-directed and random mutagenesis. Most of these investigations were carried out initially on Mb. Nine clusters of residues have been suggested as possible likely pathways for ligand escape from the interior of the protein. The most direct pathway is constituted by residues ArgCD3(45), HisE7(64), ThrE10(67), and ValE11(68), between the CD loop, the helix E, and the heme; recent analysis of kinetic data on approximately 100 Mb mutants indicates that the ligand escape route involves, by and large, the so-called histidine gate.

7
Assembly of Globin Monomers

The basic globin fold, which has been conserved throughout evolution, leads to a number of possible quaternary structures, from dimers to large assemblies. Vertebrate Hbs are tetrameric, but in the animal kingdom, globin chains can assemble into a myriad of different quaternary structures from stable dimers to very large macromolecular aggregates, like the extracellular invertebrate Hbs with a molecular mass of the order of 10^6 g mol^{-1} or higher.

Subunit interactions in assembly occur in stages and have been described as a series of coupled equilibria that are often ligand dependent. In the case of tetrameric Hb, dissociation is described in terms of the scheme:

$$\text{tetramer} \rightleftharpoons \text{dimer}$$

$$\text{dimer} \rightleftharpoons \text{monomer}$$

When dissociation is limited to the dimer stage, only symmetrical splitting is observed (i.e. $\alpha\beta$ dimers and not α_2 and β_2 dimers), reflecting the nature of molecular contacts: namely, the dissociation between like chains ($\alpha\alpha$ or $\beta\beta$) are considerably less extensive than those between unlike chains (see Table 2), of which there are two kinds. Cleavage occurs only along the $\alpha^1\beta^2$ interface (yielding $\alpha^1\beta^1$ and $\alpha^2\beta^2$ dimers) and is different for the two quaternary states, that is, it is ligand linked. In fact, the tetramer–dimer equilibrium constant of human Hb, at physiological ionic strength, is about 10^{-6} M (in terms of tetramer) for the oxy derivative and about 10^{-11} M for deoxy Hb. A variability of the tetramer–dimer dissociation constant has been reported from comparative studies of a number of Hbs from different vertebrate species. Further dissociation of the dimer to produce α- and β-chains is negligible under physiological conditions. The isolated subunit can exist as dimers (in the case of the α-chains) and even tetramers (in the case of the β-chains). It is generally assumed that dissociation of these oligomeric subunits into monomers must occur before they can combine to form $\alpha\beta$ dimers, which then aggregate to produce the fully tetrameric Hb. The overall scheme describing formation of cooperative Hb tetramer is as follows:

$$\begin{array}{ccccc} & & 2\alpha_2 & \beta_4 & \\ & & \Updownarrow & \Updownarrow & \\ 4\alpha + \beta_4 & \longrightarrow & 4(\alpha\beta) & \rightleftharpoons & 2(\alpha_2\beta_2) \end{array} \qquad (8)$$

Data on the association–dissociation reaction for human oxy Hb are summarized in Table 4.

7.1 Variations Across Species

Although Hbs from closely related species behave alike, those of distantly related ones may show marked differences. For example, fish Hbs appear to be very stable toward dissociation, even in the ligated form. Association of tetramers upon deoxygenation appears to be widespread among birds, amphibians, and some reptiles, in which species the association seems to have considerable physiological importance. Such aggregation, in fact, contributes to the Bohr effect to the extent

Tab. 4 Subunit dissociation constants (K, in M/heme) for the isolated α and β chains, and for the $\alpha\beta$ dimer and the $\alpha_2\beta_2$ tetramer, in all cases as oxygenated derivatives. The table also reports the kinetic association (k_{ass}) and dissociation (k_{diss}) rate constants. All data in 0.1 M Tris-HCl$^+$ 0.1 M NaCl$^+$ 1 mM Na_2 EDTA, pH 7.3 to 7.5 at 21.5 to 25 °C.

Reaction	*K*	k_{ass} (M^{-1} s^{-1})	k_{diss} (s^{-1})
$\alpha_2 \rightleftharpoons 2\alpha$	1.1×10^{-4} M	9.1×10^5	–
$\beta_4 \rightleftharpoons 4\beta$	4.8×10^{-16} M^3	–	0.05
$\alpha\beta \rightleftharpoons \alpha + \beta$	4.4×10^{-13} M	2.0×10^6	8.9×10^{-7}
$\alpha_2\beta_2 \rightleftharpoons 2(\alpha\beta)$	7.1×10^{-7} M	2.8×10^7	20

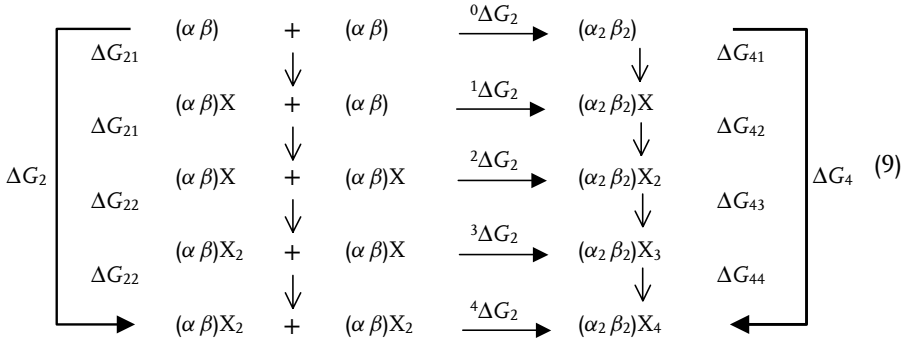
that tetramer–tetramer interaction is pH dependent. The best-studied system is that of the adult bullfrog *Rana catesbeiana*, in which two tetrameric components, B and C, associate upon deoxygenation to form aggregates that appear to be trimers of tetramers (of the form BC_2), showing an extremely low oxygen affinity, a Hill coefficient that reaches values exceeding 4, and a large contribution to the overall alkaline Bohr effect. A variant of human Hb (named Hb Olympia), in which ValB2(20) β is substituted by a methionyl residue, has oxygenation properties somewhat like those of the frog Hb (i.e. self-association in the deoxy state, cooperativity values as high as 4, and aggregation altering the Bohr effect).

In contrast to vertebrate Hbs, the invertebrate heme proteins exist as monomers, dimers, tetramers, and higher polymeric forms, and their aggregation state often depends on the heme ligand. Thus, the oligomeric state of Hbs from the sea cucumber *Caudina arenicola* varies from monomer (met Hb) to dimers (oxy and cyanomet Hb) to tetramers (deoxy Hb). The extracellular Hb of the earthworm *Lumbricus terrestris* is much larger, forming a complex of more than 200 globin monomers. An additional difference between vertebrate and invertebrate Hbs is in the quaternary structure. Thus, some tetrameric invertebrate Hbs (e.g. those of the arcid clam *Scapharca inaequivalvis* and the marine worm *Urechis caupo*) are assembled inside out. In fact, both *Scapharca* and *Urechis* Hbs have intersubunit contacts that involve the helices E, while the helices G and H (essential intersubunit contacts in vertebrate Hbs) face the solvent in that they are exposed on the outside of the molecule. However, the helix F of *Scapharca* Hb forms an important intersubunit interface, while the helix F of *Urechis* Hb is not involved in any intersubunit contact. Accordingly, *Scapharca* Hb shows cooperativity, while that from *Urechis* does not.

7.2 Subunit Interaction and Cooperativity

When a heme ligand is bound by Hb, the binding site becomes subjected to forces not present before. The strains thus set are propagated to the boundary between subunits – note that tetramer dissociation appears to take place far more readily with ligated Hb, relative to the deoxy state. This phenomenon of ligand-linked dissociation is extremely marked with Hbs from animal species, such as the lamprey (*Lampetra planerii*). In the latter case, cooperativity in the reaction with O_2 (as indicated by a value of Hill coefficient higher than 1) is exclusively dependent on oxygen-linked reversible dissociation into subunits. In the absence of O_2, lamprey Hb forms dimers (and tetramers) with low oxygen affinity; uptake of oxygen induces dissociation into monomers with higher ligand (e.g. O_2) affinity. Thus, the fraction of dimers decreases with rising oxygen saturation and, conversely, the oxygen affinity drops with increasing Hb concentration. From these observations, it follows that changes in the free energy of monomer association with heme-ligand binding must be expected. The major manifestations of the relation between cooperativity among the hemes and subunit interactions within tetrameric Hbs are the following: (1) dissociated $\alpha\beta$ dimers bind oxygen with high affinity, which is almost equal to the average affinity of the R-state Hb and the isolated α- and β-subunits, but without any detectable cooperativity; and (2) assembly of deoxy dimers into tetramers produces a large reduction in overall affinity for O_2. Since the tetramer binds the four heme ligands with

successively increasing affinity constants, the number of ligated hemes must control the interaction energy at the dimer–dimer interface (i.e. the extent to which free energy is transduced, at each binding step, into structural and energy alterations at the level of interdimer contacts). The reaction scheme that defines the free-energy changes for the O_2 binding and dimerization processes can be depicted as follows:



(9)

The values of the free-energy changes of these coupled reactions are reported in Table 5. The difference in O_2-binding free energy between the tetramer and the dimer is defined as the *total regulatory energy*, which is gained in native tetramer. From Eq. (9), it is seen that this difference $\delta G_4 - \delta G_2$ is equivalent to the difference in association energy of the ligated and unligated dimer forms, ${}^4\Delta G_2 - {}^0\Delta G_2$. Experimentally, these latter terms can be evaluated by careful association-state measurements of deoxy and oxy Hb. The regulatory energy of human Hb, calculated from data of Table 5, corresponds to 26.7 kJ mol^{-1}, that is,

$$(2\Delta G_{21} + 2\Delta G_{22}) - (\Delta G_{41} + \Delta G_{42} + \Delta G_{43} + \Delta G_{44}) \qquad (10)$$

8 Reactions with Nitric Oxide

Nitric oxide (NO) has been widely used as a ligand of the ferrous heme iron, similarly to O_2 and CO; over the years, comparison between the three gases has provided a wealth of information on the structure and function of Hb. However, the chemistry of NO is much more complex than that of other ligands of the ferrous heme iron, and interest has risen considerably since it was discovered that NO is a universal second messenger regulating circulation,

Tab. 5 Intrinsic free-energy changes (kJ mol^{-1}) in the cooperative mechanism of human hemoglobin: symbols based on Eq. (9).

Binding of heme ligand to		*Dimer–tetramer assembly reaction*
Dimers	*Tetramers*	
$\Delta G_{21} - 35.1$	$\Delta G_{41} - 22.8$	${}^0\Delta G_2 - 69.2$
$\Delta G_{22} - 35.1$	$\Delta G_{42} - 22.1$	${}^1\Delta G_2 - 47.1$
	$\Delta G_{43} - 32.6$	${}^2\Delta G_2 - 35.1$
	$\Delta G_{44} - 36.2$	${}^3\Delta G_2 - 30.9$
		${}^4\Delta G_2 - 33.2$

brain alert and defense against invaders (see *Nitric Oxide* in the *Encyclopedia*).

8.1 Reactions of NO with Various Hb Derivatives

Nitric oxide can bind to the ferrous heme iron of all known hemoproteins, yielding a simple adduct characterized by a very high stability constant ($K \sim 10^9\ M^{-1}$). However, NO can react not only with deoxy Hb (or deoxy Mb) but also with the oxygenated and the met derivatives, yielding a complex network of reactions that are summarized in Fig. 7.

The reaction of NO with oxy Hb, forming met Hb and nitrate, is a very rapid process ($k_{on} \sim 6–9 \times 10^7\ M^{-1}\ s^{-1}$ at 20 °C) competing with the straight binding to deoxy Hb ($k_{on} \sim 2 \times 10^7\ M^{-1}\ s^{-1}$ at 20 °C). The reaction between NO and HbO_2 with formation of nitrate is considered the main route to quench NO that is continuously produced in circulating blood through the physiological metabolic pathway (see Sect. 8.2). Moreover, the same reaction occurring in striated muscles and in the heart with oxy myoglobin (MbO_2) has been considered an important defense mechanism against the inhibitory effects of NO on cytochrome *c* oxidase (and thus on cellular respiration). This reaction of MbO_2 with NO is intrinsically very rapid and is made efficient by the high concentration of the pigment in the red muscles (0.3–0.6 mM). The cycle reproduced in Fig. 7 also includes the reduction of the met Hb (or met Mb), catalyzed by specific reductases.

However, contrary to O_2 and CO, NO also binds the oxidized form of Hb to produce an iron–nitrosyl complex HbFe(III)NO ($k_{on} \sim 4 \times 10^3\ M^{-1}\ s^{-1}$ and $k_{off} \sim 1 \times 10^3\ s^{-1}$), not indicated in Fig. 7. In the presence of an excess of NO, this complex undergoes reductive nitrosylation to finally generate the reduced nitrosyl adduct and nitrite:

$$\begin{aligned} &HbFe(III) + NO \\ &\rightleftharpoons [HbFe(III)NO \Leftrightarrow HbFe(II)NO^+] \\ &\xrightarrow[H_2O]{NO} HbFe(II)NO + NO_2^- + 2H^+ \end{aligned} \tag{11}$$

It should be recalled that the inorganic reaction of NO with free O_2 in solution ($k \sim 6\ M^{-1}\ s^{-1}$) is too slow to compete

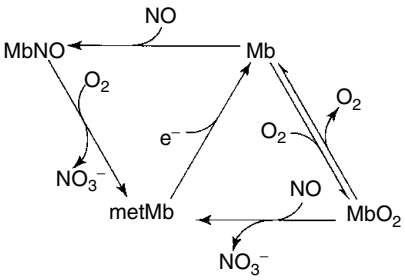


Fig. 7 The reactions of myoglobin with O_2 and NO. The primary physiological function involves the reversible binding of O_2 to deoxymyoglobin (Mb) to yield oxymyoglobin (MbO_2), which facilitates the transport of O_2 from the periphery of the cell to the mitochondria for use in respiration. MbO_2 reacts rapidly (and irreversibly) with nitric oxide (NO) to yield nitrate and ferric myoglobin (met Mb), thereby quenching free NO that might otherwise inhibit cytochrome *c* oxidase. Met Mb is reduced to Mb by met Mb reductase (e^- arrow); also, Mb binds rapidly with NO, yielding nitrosylmyoglobin (MbNO). This pathway might be of greater significance in cellular compartments with low O_2 concentrations, for example, in the immediate environment of mitochondria. In the presence of O_2, MbNO can be converted back to met Mb much more rapidly than thermal dissociation of NO, yielding nitrate again.

with the direct bimolecular reactions of NO with deoxy or oxy Hb. However, alternative reactions may come into play under different conditions, such as the paraphysiological ones where NO concentration is 10^3 to 10^6 times lower than that of O_2 and Hb. In particular, when oxygenated hemes in the quaternary R state of Hb are around $\geq$95% and when NO is present at concentrations lower than the level of vacant hemes, the unoccupied binding sites will be extremely reactive toward NO. Under these conditions, a minute amount of NO bound to the heme iron may follow an alternative chemistry, as outlined below.

It has been proposed that NO reversibly reacts with CysF9(93)β only when Hb is in the quaternary R state (e.g. oxy Hb) but not in the quaternary deoxy state; in other words, this reaction of NO to Hb should be incorporated into the MWC two-state model. If this is the case, NO would represent a third gaseous molecule (in addition to O_2 and CO_2) carried by Hb under normal conditions; this view, however, is controversial.

8.2 Physiological Implications

Nitric oxide is continuously produced in the endothelial cells through the enzymatic degradation of L-arginine by the enzyme NO synthase. This gas acts as a signal transduction molecule that mediates a variety of physiological responses, including dilatation of blood vessels, achieved by activation of soluble guanylate cyclase (a heme-containing enzyme), with an increase in the intracellular cyclic guanosine-monophosphate concentration and thus, relaxation of vascular smooth muscles. The supposedly rapid conversion of NO to biologically inactive metabolites in blood (e.g. nitrate) formed the rationale for inhalation NO therapy, because the short half-life ($\sim$2 ms) of NO in blood should confine its effects to the pulmonary circulation. Erythrocytes may be considered to be a major sink for NO by virtue of the quick oxidation reaction of NO with oxy Hb (see Sect. 8.1) to produce met Hb and nitrate, due to (1) the speed of this bimolecular reaction (half-life about 1 µs, according to extrapolation of the *in vitro* data); and (2) the high concentration of oxy Hb in blood, which is in the millimolar range (2 mM in tetramers), to be compared with endothelium-derived local-level of NO that reaches only nanomolar concentrations.

Nitric oxide was also shown to be transported bound to sulfhydryls groups through a process called *nitrosation*, occurring by reaction of the nitrosonium cation and the deprotonated sulfhydryls:

$$R{-}S^- + NO^+ \rightleftharpoons R - SNO \qquad (12)$$

This reaction occurs quite easily not only with reduced but also with oxidized glutathione, which is at high concentration in the erythrocytes ($\sim$2.5 mM). The same reaction was shown to occur with the CysF9(93)β of human HbA, the rate of formation and dissociation of β93-SNO being dependent on the quaternary state of Hb (whether R or T). According to this hypothesis, NO binds cooperatively to the minor ($\sim$1%) population of deoxygenated heme in oxygenated erythrocytes present in the arterial circulation, forming iron–nitrosyl–Hb; the NO group is then transferred (through a one-electron oxidation) to CysF9(93)β to produce its S-nitro derivative ($<$50 nM *in vivo*), which dissociates NO upon deoxygenation in the peripheral tissues and elicits vasorelaxation *via* transnitrosation reactions to low molecular

mass thiols (such as glutathione, yielding *S*-nitroglutathione) or high molecular mass sulfhydryls (specifically, the anion exchanger or band 3 in the erythrocyte membrane).

This hypothesis is opposed on the basis of the argument that two phenomena would combine to make the reaction of NO with Hb 10^6 times slower *in vivo* than *in vitro*: (1) adjacent to the endothelium, the blood flow creates an erythrocyte-free layer, whose dimension (proportional to the vessel diameter) modulates the amount of NO that diffuses into smooth muscle layer; and (2) the rate of NO scavenging by erythrocyte is 500- to 1000-fold smaller than that of an equivalent concentration of cell-free Hb, possibly due to the existence of multiple diffusional barriers for NO surrounding red blood cells (unstirred plasma layer, laminar-flowing blood, and erythrocyte membrane matrix). Therefore, the local concentration of NO (~400 nM) produced by endothelial cells is in large excess of that required to activate guanylate cyclase (the level for its half-maximum activity being ~20 nM), thus ensuring that sufficient NO reaches its target enzyme and induces smooth muscle relaxation.

Support and dissent to both models mostly depend on the wide spectrum of analytical approaches employed to measure NO and nitrosothiols, methods that often yield divergent values and thus lead to conclusions with many aspects being disputed. In particular, the main dissent rests on the similarity or difference in levels of *S*-nitrosothiols and HbFe(II)NO, between arterial and venous blood: thus, in contrast with proponents of the model assigning an essential physiological role to – SNO transport, opponents report no artery-to-vein gradient.

9
The Globin Gene and its Biosynthesis

In humans, the initial ζ (α-like) and ε (β-like) embryonic subunits, synthesized in the yolk sac during the third through eighth week of gestation, are gradually replaced by α- and γ-chains so that the original Hb Gower-1 is replaced, first by Hb Gower-2 and Hb Portland and finally by HbF (see Sect. 3). At about seven weeks of gestation, when liver and spleen become the major sites of erythropoiesis, HbF accounts for about 50% of total Hb. Synthesis of β-chains, minor at first, begins to accelerate around the thirtieth to fortieth weeks of pregnancy (see Fig. 8a). Within eight weeks after birth, when erythrocyte production has shifted from liver and spleen to bone marrow, mainly α- and β-chains are synthesized. At 6 months after birth, the adult $\alpha_2\beta_2$ form has essentially taken over, along with the minor $\alpha_2\delta_2$ component (Fig. 8B).

Each of these Hbs, synthesized during the development from embryo to fetus to infant (Fig. 8b), consists of two α-type and two β-type subunits. The α-type (α, ζ) and β-type (β, γ, ε, δ) families of human genes are clustered, respectively, near the telomere of the short arm of chromosome 16 and on the short arm of chromosome 11. Each globin gene in a cluster, like most other eukaryotic genes, possesses a mosaic structure in that it contains three coding blocks (exons) separated by two intervening sequences (introns) of DNA (Fig. 9). It is worth noting that the gene encoding neuroglobin (located in chromosome 14), as well as that encoding cytoglobin (located on chromosome 17), have three introns like the gene of plant Hb (see also Sect. 1). Exons, introns, and the flanking regions (whose directions are indicated by 5′ or upstream and 3′ or downstream, relative

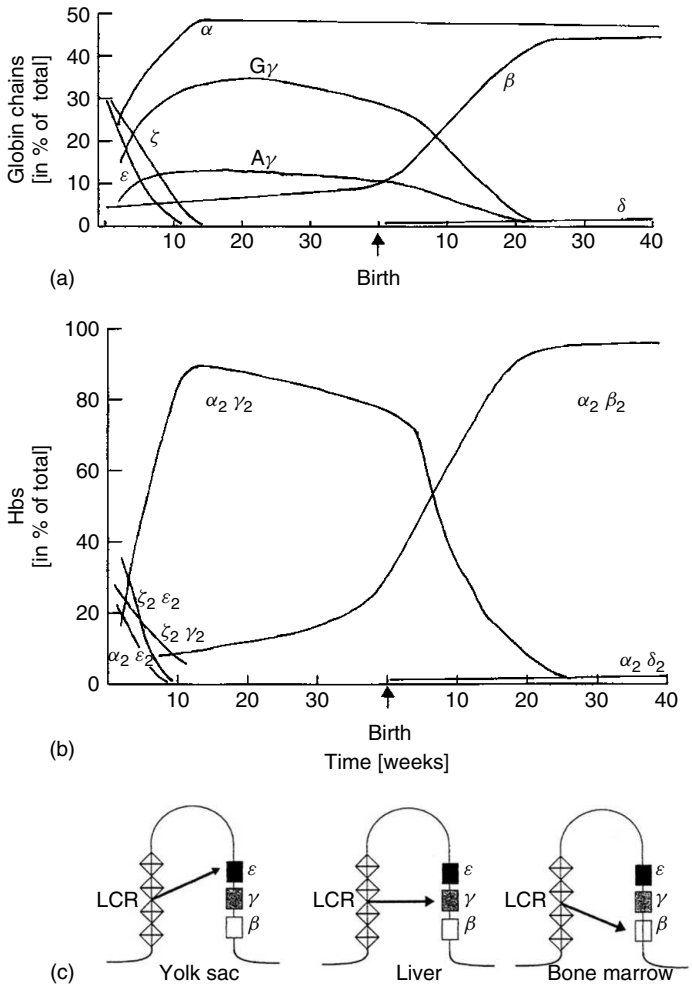

Fig. 8 Relative amounts of globin subunits (a) and Hb tetramers (b) at different stages in the development of the human embryo, fetus, and infant. Modifications in the pattern of globin gene expression are controlled by a regulatory element, located at the 5′ flanking end and called *locus control region* or LCR. In the absence of an interaction with LCR, individual globin genes are either inactive or very poorly expressed. In a series of interactions of LCR with downstream genes of the β-type gene cluster (c), the mutually exclusive binding at each development stage is indicated by the arrows.

to transcription start site of each gene) are transcribed into nuclear mRNA precursors (pre-mRNA). While pre-mRNA is still in the cell nucleus, the intervening sequences are excised and the terminals of the exonic sequences religated to yield the mature mRNA (a process termed *splicing*). Lastly, mRNA is translated into globin. Conserved nucleotide sequences, important for gene function and regulation, are found just

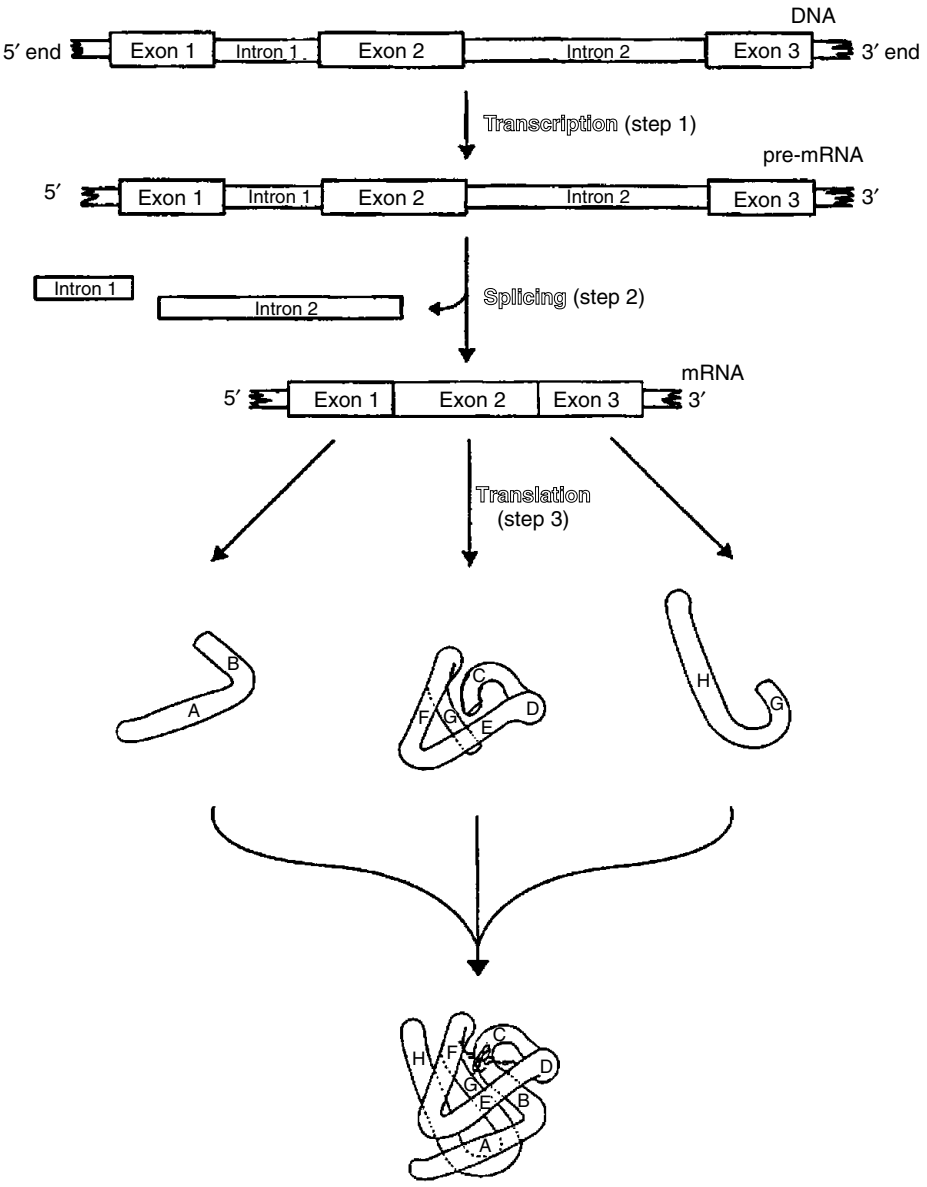

Fig. 9 The mosaic or exon–intron structure of a globin gene encoding a typical polypeptide chain of mammalian Hb or Mb. From the gene, a primary transcript or pre-mRNA is synthesized (step 1); the intervening sequences or introns are then excised (step 2) by splicing to yield the mature mRNA; this is translated (step 3) into the polypeptide chain, which spontaneously adopts the typical globin fold. Three globin "domains" corresponding to the three exonic transcripts are schematically illustrated.

upstream of the mRNA coding blocks (i.e. at the 5′ end), at the exon–intron boundaries, and at the 3′ end of the mRNA coding sequences. Moreover, expression of individual genes in a cluster, as development from embryo to newborn proceeds, is dependent on cis-acting elements of gene switching as well as trans-acting proteins.

Cis-linked regulatory elements include promoters, enhancers, silencers, insulators, boundary elements, and the locus control region or LCR (see Fig. 8c). The human β-globin LCR – a region of DNA located from about 6 to 22 kb upstream of ε-globin gene – is composed of five domains (called *hypersensitive sites* or HS) of nucleosome disruption that exhibit extremely high sensitivity to DNase I digestion, thereby rendering the region accessible to transcription and chromatin remodeling factors: four of these HS are erythroid specific, whereas one is ubiquitous. The entire β-globin locus remains in an inactive DNase-I-resistant chromatin conformation in cells in which the globin genes are not expressed; in erythroid cells, the entire locus shows a higher degree of sensitivity to DNase I, indicating that it is in a more open and accessible chromatin configuration. In particular, in embryonic cells, the susceptibility to the digestion attack is higher in the region containing the ε-globin and γ-globin genes, whereas it is the zone where the δ-globin and β-globin genes are located that is more sensitive in the adult erythroid cells.

However, efficient transcription of genes requires a high local concentration of relevant trans-acting factors. Nuclear compartmentalization provides an effective means to locally enhance the level of rapidly moving trans-acting proteins, a process that can be achieved by spatial clustering of chromatin-associated binding sites for cognate transcriptional factors.

Some erythroid-specific factors are targets of histone acetyltransferases and some exist as phosphoproteins, indicating that their activities are regulated by posttranslational modification and that they may be involved in chromatin remodeling of the β-globin locus.

Three main models have been proposed to elucidate the regulation mechanism of the LCR: (1) in the looping model, the LCR acts as an integral unit, forming interactions with transcription factors and the core-flanking sequences; this structural unit loops in such a way as to directly associate with gene-proximal promoter and enhancer elements, thereby activating the appropriate gene expression (Fig. 8c); (2) according to the linking model, the LCR promotes the formation of a chain of transcriptional facilitator proteins that extends along the chromatin fiber between the LCR and the globin gene family to activate the individual gene promoter; and (3) in the tracking or scanning model, erythroid-specific and ubiquitous transcription factors and cofactors bind recognition sequences in the LCR, forming an activation complex that migrates – or tracks – linearly along the DNA helix of the locus; when such a complex encounters the basal transcription machinery located at the correct (according to the developmental stage) promoter, the complete transcriptional apparatus is assembled and transcription of gene initiates.

Chromosome organization is such that the members of each globin family are arrayed from amino-terminal coding (5′) to carboxy-terminal coding (3′) sequences (see Fig. 9). In the α-family genes, the three exons code for residues 1–31, 32–99, and 100–141 respectively; in the β-family genes, the corresponding positions are 1–30, 31–104, and 105–146. Even though the breaks occur in all chains at identical

peptide bonds along the helical segments (i.e. between residues B12 and B13 and between G6 and G7), they do not mark the boundaries of clearly defined structural domains; they do, however, correspond to smaller compact modules. Thus, the central exon (exon 2 in Fig. 9) encodes a module that provides a competent heme-binding site (helices E and F) and the $\alpha^1\beta^2$ sliding contact (helix C and FG corner); such a module binds heme tightly and specifically, but ligand-linked structural fluctuations (as observed in the protein fragment encoded by the central exon of the present-day Mb gene) are large enough to yield an unstable O_2 complex. Addition of the two terminal polypeptide modules (coded by exon 1, which corresponds to helices A and B and constitutes a scaffolding for the heme pocket, and exon 3, which provides helices G and H and contributes most of the $\alpha^1\beta^1$ packing contacts; see Fig. 9) reduces the structural degrees of freedom of the central module; the ensuing damping effect in the amplitude of the conformational fluctuations stabilizes the efficiency of the holoprotein as a unit of biochemical machinery.

The α-type gene cluster contains three functional genes (ζ, $\alpha 1$, and $\alpha 2$) and three pseudogenes indicated by the prefix ψ ($\psi_{\alpha 1}$, $\psi_{\alpha 2}$, and ψ_{ζ}). Pseudogenes have sequence homology to the functional genes but are defective in some essential coding and/or regulatory regions and thus cannot be expressed in a globin chain. The β-type gene cluster has five active genes (ε, G_γ, A_γ, δ, and β) and one pseudogene (ψ_β). The two fully functional and nearly identical α ($\alpha 1$ and $\alpha 2$) and γ (G_γ and A_γ) genes possibly reflect their duplication during evolution.

In these gene families, all vertebrate globins are encoded in the same order in which they are expressed during the development: $\varepsilon \rightarrow \gamma \rightarrow \delta, \beta$ in the β-cluster, and $\zeta \rightarrow \alpha$ in the α-cluster.

Throughout development from embryo to infant, a balance in expression between α-like and β-like globin genes is maintained, yielding fully functional Hb tetramers (Fig. 8b). However, the α- and β-globin genes are regulated in distinctly different ways. In particular, the α-globin gene does not require an added enhancer for expression in transfected erythroid and nonerythroid cells; in contrast, the β-globin gene requires the presence of a viral enhancer in cis for transient expression in nonerythroid cells. Hb synthesis is coordinated to minimize the accumulation of free subunits that form cytotoxic precipitates. A chaperone, known as *α-Hb Stabilizing Protein*, prevents *in vivo* precipitation of free α-chains, suggesting that α-globin levels and their incorporation into Hb tetramers is controlled posttranslationally. This is in contrast to β-globin concentrations, which are largely governed via regulation of transcription.

However, the regulatory mechanisms do not take into account whether the genes, which are yet to be activated, are functional or not. Consequently, when the programmed developmental time for the activation of globin gene is reached, the transcription machinery will be positioned even when the gene is defective and unable to produce any protein.

Alteration of the balanced synthesis of globins in the two clusters leads to a very important type of molecular disease called *thalassemia*. In β-thalassemia, a partial or complete deficiency of β-chains is associated with a prolonged biosynthesis of the fetal γ-chains (yielding HbF or $\alpha_2\gamma_2$) and possibly with the accumulation of free α-chains, which associate in the insoluble aggregates, with toxic effects on the development of erythroblasts. In α-thalassemia,

a relative deficiency in α-subunit biosynthesis results in an excess of γ- or β-chains, which assemble into γ_4 (Hb Bart's) and β_4 (HbH) homotetramers respectively.

10 Evolutionary Considerations

The essential features of the globin fold (i.e. the overall three-dimensional structure of the protein, with its ensemble of α-helical and nonhelical stretches; see Fig. 1) from very diverse organisms – ranging from mammals to insect and plant root nodules – are highly conserved, even when the amino acid sequences have diverged until similarity is virtually undetectable. This finding suggested to M. F. Perutz that the spontaneous folding of the globin chain implies stereochemical similarities in sequence, which satisfy the overall structural configuration in spite of large differences in amino acid composition; this led to the hypothesis that the globin family has evolved by divergence from a common ancestral gene (see Fig. 10). Moreover, the discovery of Hbs in virtually all kingdoms of organisms has suggested that the ancestral gene is ancient. Various estimates place the time of duplication of the globin genes from their single ancestor during early vertebrate evolution at approximately 800 million years ago (see Fig. 10). Although the resolution of the phylogenetic tree is poor, evolutionary analysis suggests that neuroglobins do not group with

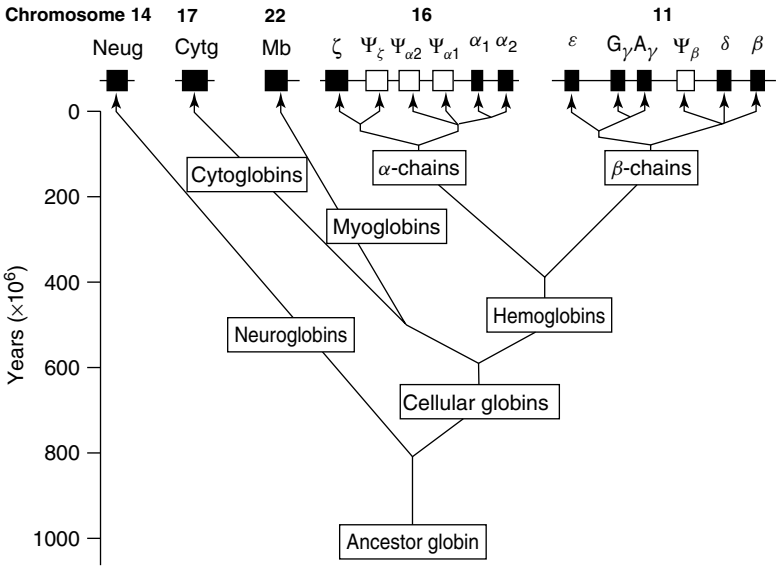

Fig. 10 Possible evolution of the globin genes, as deduced from DNA and amino acid sequence differences. The arrangement of the globin genes and pseudogenes (denoted by the prefix ψ) in humans is shown at the top, together with the indication of the chromosome where the gene is located. Estimated times of divergence in millions of years are only approximate. The high similarity between two α-genes (α_1 and α_2) and between genes G_γ and A_γ indicates that their duplication must have occurred quite recently in evolutionary time. The G_γ and A_γ genes produce chains with glycine or alanine, respectively, at position H14(136) (see also Table 1).

vertebrate Hbs and Mbs (thought to have diverged 500–600 million years ago) and must be older. A distinct position of neuroglobins is also suggested by exon–intron structure (see Sect. 9). The very early ancestor to vertebrates contained a single ancestral gene. On the basis of the antiquity of neuroglobin, it has been proposed that the last common ancestor to all vertebrates most likely possessed two globin loci. Thus, duplication of the ancestral locus resulted in two loci, developing into two different types of globin: neuroglobin and cellular globin (see, Fig. 10). A further duplication of cellular globin locus allowed the development of the myoglobin and cytoglobin loci, on one hand, and of Hb locus, on the other. The Hbs obtained their function in the circulatory system of the jawed vertebrates (fish, amphibians, and reptiles) after their divergence from the lineage leading to the myoglobins and cytoglobins, an event probably related to an increase in body size and to the development of an efficient circulatory apparatus. Myoglobins and cytoglobins separated later. From the phylogenetic data, it is unclear whether this occurred before the jawed vertebrate diverged from the jawless vertebrates or agnathans (lampreys and hagfish). In the Hb locus, gene duplication gave rise to a cluster encoding several monomeric Hbs, as found in agnathans. This allowed the specialization of individual genes in α-type or β-type Hbs that are found closely linked in the same locus (as in poikilothermic jawed vertebrates). It is thought that a common ancestral globin gene gave rise to distinct α- and β-globin genes through duplication events, followed by the separation of the α- and β-genes to different chromosomes, as they are in homeothermic vertebrates (birds and mammals). The original α-gene in turn subdivided into α and ζ somewhere in the reptilian line; on the other hand, the original β-gene differentiated into adult β and fetal γ during the rise of mammals. The original γ-gene itself later produced both γ and ε, whereas primates generated a δ-gene from the β-gene. During the long evolution of globin, only two positions (F8 and CD1) have remained invariant (i.e. have been found in all Hbs): the proximal histidine F8 and phenylalanine CD1, which wedges the heme into its pocket (see Fig. 2). This means that to ensure the satisfaction of similar stereochemical requirements, the vast majority of amino acid replacements have been conservative, that is, at a given position in the sequence, a residue has been replaced by many others (depending on the species) of the same general class. Since these mutations do not appear to be correlated with any fundamental change in the functional properties of Hb, they are called ''neutral'' and simply reflect accumulation of random nucleotide substitutions that occur at low frequency during DNA replication. It is expected, of course, that highly deleterious mutations will have been weeded out by natural selection.

Analysis of available sequences (>300) shows that evolutionary divergence has been constrained primarily by an almost absolute conservation of the hydrophobicity of the residues buried in the helix-to-helix and helix-to-heme contacts. Survival of mutant proteins in the globin family has been restricted to those that maintain the basic globin fold, tolerating variations not only in residues occupying surface positions but also in those buried in the molecule. Changes in surface residues are sometimes reflected in radically different quaternary structures with novel subunit contacts (see Sect. 7), typical of some invertebrate Hbs, which maintain reversible oxygen binding and cooperativity.

As for other proteins, the more distant two globins are in the phylogenetic tree, the more dissimilar the amino acid sequences of shared proteins will be. Thus, if the comparison between members of the globin family is restricted to vertebrates, the number of common residues is relatively high. Indeed, precisely 27 amino acids in the α-subunits and 18 amino acids in the β-subunits have remained invariant (based on the amino acid sequence of 32 species), and most of them are located at sequence positions responsible for efficient oxygen delivery: 14 are heme contacts, 16 are intersubunit contacts essential for allosteric mechanism, 8 are involved in hydrogen bonds or salt bridges within the subunits or at the $\alpha^1\beta^1$ interface, 6 are involved in internal nonpolar contacts, and a single proline serves to turn the BC corner in the β-subunits.

It has been estimated that changes in the Hb genes accumulated at an average rate of one residue per α- or β-subunit every 2 to 3 million years. This notion is in line with the general ideas of evolution, illustrated by the observation that, in the β-chains, there are eight differences between man (*Homo sapiens*) and rhesus monkey (*Macaca* spp.), 24 differences between man and cow, 45 differences between man and chicken, and 91 differences between man and shark.

However, a close scrutiny of available data for calculating evolutionary rates from the distribution of mutations on the genealogical tree (all corrected with assumptions about the supposed nature of molecular evolution) does not help in discriminating unequivocally between two possible conclusions: (1) the average rate of accumulation of mutations in globin sequences has remained approximately constant from the ancestral to the present-day Hb genes; or (2) genetic diversification occurred in various phases with discontinuous evolutionary rates.

The first conclusion is easier to explain by the neutralist theory, according to which most evolutionary changes at the molecular level and most of the variability within a species are caused not by selection but by random drift of mutant genes that are selectively equivalent. In other words, evolutionary rates are essentially determined by the structure and function of the molecules and not by environmental conditions or population size. The approximate constancy of the evolutionary rate for globin genes is supported by comparison of the divergence between human α- and β-chains and the divergence between the α-chain of carp and the β-chain of man (see Table 6). The two α-chains and the human β-chain differ to roughly the same extent. Since the sequence of the α-chain of man differs from that of carp in about half the positions, the α-subunits of the two distinct lineages (one leading to carp and the other to man) appear to have accumulated mutations independently and at approximately the same rate over a span of 500 million years (i.e. since gene duplication between α- and β-chains arose).

Although the biological-clock hypothesis proved to be a useful tool for the quantitative investigation of the time evolution of biological processes at the level of proteins, the clock itself does not appear to be as regular as a simple Poisson process. For example, the clock seems to have changed its rate during evolution while (or when) a tetrameric Hb was first assembled, starting from an ancestral monomeric globin. In fact, analysis of the reconstructed genealogical tree of globin chains (see Fig. 11) shows an acceleration–deceleration pattern of molecular evolution between ancestor and descendants, evidence favoring positive selection

Tab. 6 Number of differences between the amino acid sequences of human α- and β-chains compared with the number of differences between the sequences of α-chain from carp and human β-chain.

Type of change in the genetic code	*Human α- versus human β-chain*	*Carp α- versus human β-chain*
No change	62	61
One nucleotide	55	49
Two nucleotides	21	29
Addition or deletion of a residue	9	10
Total	147	149

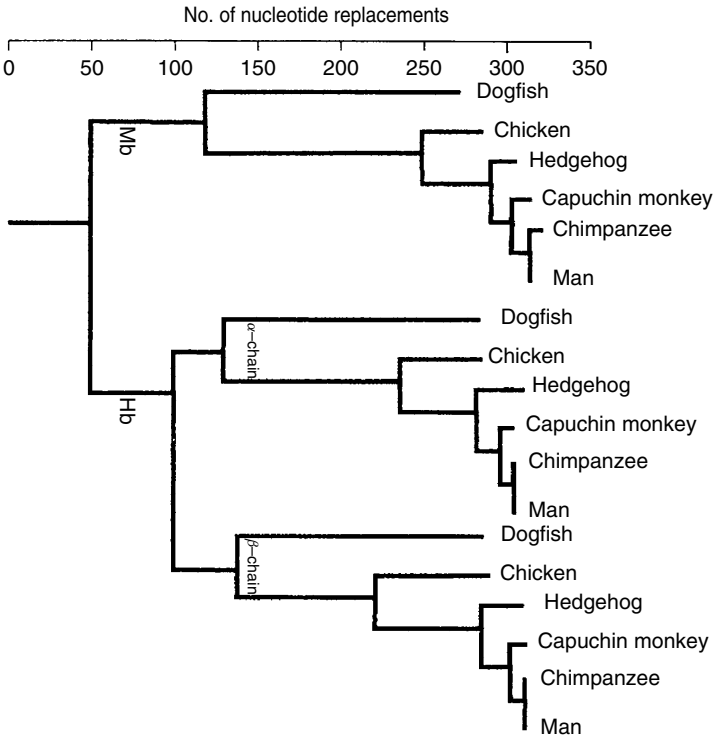

Fig. 11 Acceleration–deceleration pattern in rates of globin evolution during vertebrate phylogeny. The portions of the genealogical tree depict the phyletic distance (i.e. the number of sequence substitutions that have occurred as estimated from sequence data of 159 globins) from the early vertebrates to the present.

rather than neutral fixation. Thus, the selectionist or Darwinian view maintains that for a mutant allele to spread through a species, it must carry some selective advantage; it is also presumed that at each stage in the evolution of the tetramer, the portion of the molecule just being developed accepted nucleotide changes

more rapidly than the regions that had already been evolved or had yet to evolve. As stated by R. E. Dickerson, in the evolution of globin, there seem to be periods when sequence changes were predominantly a consequence of natural selection; on the other hand, after satisfactory selection of a globin suited to its physiological role, the rate of accumulation of sequence changes appears to have settled down to a nearly constant value – a behavior that is hard to reconcile with anything but random fixation of near-neutral mutations. In conclusion, neither positive selection nor neutral drift is the sole force directing changes in globin during evolution, but each model seems applicable and relevant at different time spans during the evolution of globin.

11
Hemoglobin Variants

11.1
Nature of Mutants

Several hundred mutant Hbs (882 up to the year 2004) within the human population have been isolated and chemically characterized: variants of α-subunits relative to those of β-subunits are approximately in a ratio of 1 : 2. In most cases, the abnormality consists of the replacement of a single amino acid residue per $\alpha\beta$ dimer; all these modifications are consistent with single-base substitution in DNA coding for the globin subunits. Some abnormal Hbs have residues deleted or inserted (168 variants); in others, the subunits are cut short or elongated (12 variants); others are constituted by fusion of two different subunits (9 variants); and yet others show more than one point mutation in the same polypeptide chain (15 variants). Of the large number of Hb mutants, a significant fraction has deleterious effects on health (see Table 7). Various databases of Hb variants have been developed, with increased capacity for sophisticated queries and prompt updating (e.g. http://globin.cse.psu.edu).

11.2
Molecular Basis of Hemoglobin Diseases

Pathological symptoms in the carriers of Hb diseases have been associated with altered oxygen affinity (causing polycythemia if it is raised or cyanosis if it is lowered), decreased stability of the protein (determining hemolysis and clumps of denatured Hb called *Heinz bodies*), an increased tendency to form ferric Hb (mainly producing cyanosis), and abnormal intracellular polymerization (inducing a contorted banana- or sickle-shaped erythrocyte). In many cases, these biochemical abnormalities have been interpreted with the help of the three-dimensional structure.

Many of the structural abnormalities giving rise to clinical symptoms are clustered around the heme pockets or are in the vicinity of the $\alpha^1\beta^2$ interface, so important in allosteric transitions. Some of the typical structural changes leading to abnormal Hbs are as follows:

1. A common structural pattern causing an increase in O_2 affinity is the loss of hydrogen bonds, salt bridges, or nonpolar interactions that stabilize the Hb tetramer and the T state in particular; moreover, some mutations increase O_2 affinity because they impair BPG interaction by modifying its binding site.
2. Unstable Hbs (128 variants) usually involve (1) an opening of heme pocket, loss of heme, and subsequent precipitation of globin; (2) insertion of a proline into a helix, where a kink is introduced

Tab. 7 Selected list of point mutations determining abnormal human Hbs.

Residue	*Replacement*	*Common name*	*Comments*
		Change in oxygen affinity	
CE3(45)α	His → Arg	Fort de France	Oxygen affinity ↑; stabilization of R state
G2(95)α	Pro → Ser	Rampa	Oxygen affinity ↑; tetramer dissociation
HC3(141)α	Arg → His	Suresnes	Oxygen affinity ↑; destabilization of T state
E18(74)β	Gly → Asp	Shepherds bush	Oxygen affinity ↑; decrease of BPG association
G4(102)β	Asn → Thr	Kansas	Oxygen affinity ↓; stabilization of T state
		Heme loss and/or denaturation	
H19(136)α	Leu → Pro	Bibba	Unstable; proline disrupts helix H
CD1(42)β	Phe → Ser	Hammersmith	Unstable, loss of heme; water attracted into heme
B14(32)β	Leu → Arg	Castilla	Unstable; positive charge in molecular interior
		Molecules with iron permanently in ferric oxidation state	
E7(58)α	His → Tyr	M Boston	Fe (III) ligated to Tyr instead of His
E14(70)β	Ala → Asp	Seattle	Stabilization of Fe (III) by negative charge of Asp
		Sickling	
A3(6)β	Glu → Val	S	Sickling; fit of Val into EF cleft of another tetramer
GH4(121)β	Glu → Lys	O Arab	Enhancement of sickling in S/O heterozygote; residue 121 β lies close to residue 6 β and Lys increases interaction between tetramers

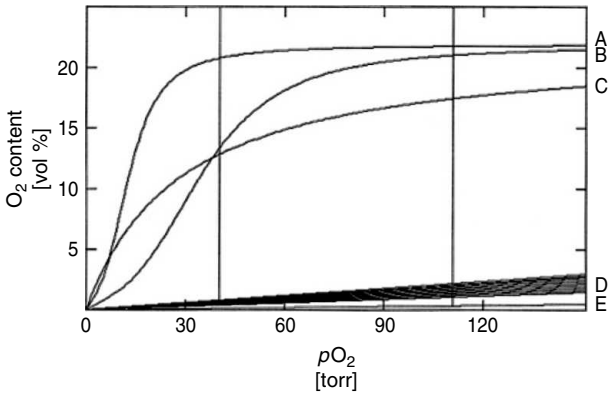

Fig. 12 The O_2 content of blood and some O_2 carriers as a function of O_2 partial pressure under physiological conditions (pH 7.4, 37 °C): A, native Hb stripped from BPG; B, whole blood; C, pyridoxylated, glutaraldehyde-polymerized Hb; E, plasma. Area D comprises the range of commonly employed perfluorocarbons (compounds forming fine and stable emulsions with water). The vertical lines indicate venous (40 torr) and arterial (105 torr) oxygen pressure. It can be noted that release of O_2 by a solution of stripped, native Hb is very small, while for polymerized pyridoxylated Hb, it is approximately half that of blood.

that usually disrupts the tertiary structure; or (3) unfavorable removal of a nonpolar side chain on the molecular surface (which excludes the interior of the protein from the surrounding water), introduction of a charged group inside the molecule, or deletion of single residues or segments of polypeptide chains. All these events can disrupt the basic folding of Hb.

3. The M (for met Hb) mutants are the class of Hbs in which the Fe atom of one type of subunit is permanently oxidized as a result of the replacement of a heme contact residue; the most common mutations are the substitution of either the proximal histidine (HisE7) or the distal histidine (HisF8) by a tyrosine in the α-, the β-, or the γ-subunit.
4. In general, the mutations that lead to abnormal Hb behavior are not located on the exterior of the tetramer; yet, the replacement of a surface glutamate at position A3(6)β with a hydrophobic valine in HbS or sickle-cell mutant (the most prevalent Hb variant worldwide) has deleterious effects. Upon deoxygenation of a concentrated Hb solution, HbS tetramers aggregate into a gel, distorting and rigidifying the erythrocytes into a variety of bizarre shapes. As a consequence, the red cells may not be able to transverse the microcirculation vessels, with transient to permanent blockage of local oxygenation. When this happens, the resulting organ damage is a major cause of the morbidity and mortality of sickle-cell anemia. The key to erythrocyte sickling in HbS is the presence of a hydrophobic pocket located between helices E and F and made up of PheF1(85)β and LeuF4(88)β, which binds ValA3(6)β; upon oxygenation, the helix F motion of the β-subunits pulls the PheF1(85)β of one tetramer away from potential contact with the ValA3(6)β side chain of a second tetramer, leading to dissociation of the fibrils into oxygenated HbS tetramers.

12 Hemoglobin Solutions as Blood Substitutes

Many blood substitutes should be more properly called O_2 carriers since they provide O_2 transport and volume replacement but do not perform other functions of blood (e.g. facilitating coagulation and immune responses). They are life-support systems able to dissolve (and thereby transport) large amounts of O_2; this mode of operation is at variance with simple plasma expanders, which contain dissolved O_2 at low concentration ($\approx$0.3 mM). Among potential O_2 carriers, attention has been focused on perfluorocarbons (synthetic compounds that reversibly dissolve O_2) and a variety of Hb preparations, either free in solution or encapsulated into lipid vesicles. To be efficient, perfluorocarbons have to be used under high O_2 pressure (see Fig. 12), otherwise, the amount of O_2 transported is much too low; moreover, they are immunotoxic.

Unprocessed solutions of Hb are unsuitable as O_2 carriers for several reasons. First of all, Hb quickly disappears from plasma, partly through formation of a complex with the plasma-protein haptoglobin (mainly cleared by the liver with a half-life of 10–30 min) but mostly through direct filtering off by the kidney, with a half-life of 1 h. The direct elimination though the kidney is possible because in dilute solutions, tetrameric Hb easily dissociates into free $\alpha\beta$ dimers; the kidney is permeable to proteins of molecular mass $<40\,000$ g mol^{-1}, unless very highly charged.

Second, O_2 release to tissues is poor as a result of the high affinity of Hb dissolved in plasma, which is stripped from BPG, the allosteric effector that modulates the efficiency of oxygenation. At 37 °C and pH 7.4, $p_{1/2}$ would decrease from the physiologically desirable level of about 26 torr to about 10 torr, which is too low for effective delivery (see Fig. 12).

Finally, unprocessed solutions of Hb are not suitable as O_2 carriers because the isosmotic concentration of Hb dissolved in plasma (70 g dm^{-3}) is about half that of normal blood (150 g dm^{-3}). To overcome these drawbacks, several covalent modifications of Hb have been described to produce Hb-based blood substitutes, with the idea of capitalizing on their potential advantages, such as, the Hb solutions can be used immediately without the need for blood group typing, they can be stored in a ready-for-use formulation for years and heat-treated, thus eliminating the risk of viral transmission.

Thus, the first generation of Hb-based O_2 carriers were designed to prevent dissociation into dimers and, therefore, to prolong the half-life of Hb within circulation. The molecular mass of chemically engineered O_2 carriers has been increased by (1) intra- and inter-tetrameric cross-linking with glutaraldehyde or glycolaldehyde; (2) conjugation to dextran and polyethylene glycol derivatives; and (3) protein engineering by fusion of the two α-subunits. Moreover, to decrease the O_2 affinity of Hb and, therefore, to improve unloading to the tissues, covalent attachment to the α-subunits of pyridoxal 5′-phosphate (which is known to mimic the functional effect of BPG) or specific chemical changes [e.g. Asn G10(108)$\beta \rightarrow$ Lys] obtained by site-directed mutagenesis, were realized. Other compounds, such as bis(3,5-dibromosalicyl)fumarate and *nor*-2-formylpyridoxal-5′-phosphate, reduce the O_2 affinity and, at the same time, stabilize the tetramer.

Large-scale polymerization (such as that obtained by glutaraldehyde treatment) not only prolonged the vascular retention of the Hb molecules but also lowered the osmotic activity by decreasing the number of particles per unit volume. In particular, the isosmotic concentration in plasma was increased from 70 g dm^{-3} (of free Hb) up to 150 g dm^{-3} (i.e. the Hb level in blood of healthy subjects). The latter system showed some disadvantages, however, since the solution viscosity was much higher than that of blood. Under chosen conditions, glutaraldehyde-treated Hb forms polymers containing two to eight tetramers, having an isosmotic concentration of 100 g dm^{-3} and a viscosity lower than that of blood; the vascular retention of this compound in rabbits was about 20 h, a time sufficient for several clinical applications. In fact, when the Hb derivative is used solely for the purpose of O_2 transport, as in the prevention of cardiac ischemia (e.g. during balloon angioplasty), a relatively short half-life (5–10 h) may actually be useful.

Identifying alternative sources of Hb has been an additional, although not secondary problem, since supply of the human protein is limited. Therefore, the use of Hb from other mammals (such as ox, pig, and mouse) has been considered since the Hb molecule is scarcely antigenic; however, the possibility of anaphylactic reactions after repeated applications is not unlikely, even though the antigenic response in humans can be minimized by modification of Hb with polyethylene glycol.

However, severely adverse outcomes were noted in clinical trials with first-generation Hb-based O_2 carriers, which

were therefore dropped in favor of developing second-generation products. In fact, outside the erythrocyte, Hb appears to be inherently toxic, being able to generate highly reactive O_2 species (mainly, superoxide and peroxide) and to interfere with the modulation of blood pressure. Thus, met Hb levels of polymerized Hb can increase in 24 h from an initial 3 to 40%. Harmful reactive O_2 species, which are by-products of Hb auto-oxidation, are known to produce cellular damage and constitute an important concern in the use of modified Hb as reperfusion agents. Moreover, the reaction of met Hb with H_2O_2, produced during the process of auto-oxidation, is known to proceed via the formation of the highly reactive ferryl Hb (i.e. HbFe(IV)), a short-lived chemical species that peroxidizes lipids, degrades carbohydrates, and modifies proteins as well as nucleic acids. Moreover, extracellular oxy Hb – in contrast to that encapsulated in erythrocytes (see Sect. 8) – is highly vasoconstrictive and the resulted hypertension is a significant side effect of most Hb-based blood substitutes. All these effects can explain some of the unique toxicological effects associated with the use of the first-generation O_2 carriers in the clinic, on the basis of chemically modified Hb.

Strategies aimed at solving the above-reported toxicities form the basis for the second-generation Hb prototypes of blood substitutes being able to safely carry O_2. Thus, intraerythrocyte antioxidant enzymes (such as superoxide dismutase and catalase) or water-soluble vitamin E analogs, have been cross-linked to Hb in the attempt to control Hb oxidative side reactions, obtaining amelioration of free-radical-mediated injury to cellular systems. Moreover, the active sites of Hb subunits have been engineered (e.g. LeuB10 of both chain types replaced with large aromatic amino acids) in order to reduce the rate of NO binding (by $\geq$30-fold), and therefore the NO scavenging activity, while still retaining efficient O_2 transport.

Keywords

CpG and CpG island
CpG is a dinucleotide formed by C followed by G, and CpG islands are genomic regions unusually rich in CpGs and found before genes and especially genes with ubiquitous expression patterns.

Founder Mutation
A mutation traceable to a common ancestor and found relatively frequently in some populations.

Frameshift
Mutation of a coding sequence due to loss or addition of one or two nucleotides or multiples thereof. This alters the amino acid sequence from the point of mutation onward and frequently leads to premature termination of the encoded polypeptide.

Male-driven Evolution
A situation where the male, by having a higher mutation rate than the female, contributes a greater proportion of the variation acted on by natural selection.

Missense
Mutation resulting in the substitution of one amino acid for another.

Mutational Load
The sum of the deleterious mutations present in a zygote.

Nonsense
Mutation converting a codon specifying an amino acid into one determining the end of a polypeptide sequence.

Uninemic
Of events affecting a single molecule of double-stranded DNA as that present in a chromatid or a prereplication chromosome.

Zygote
The cell formed by the fusion of a male and female gamete and representing the origin of a new potential individual.

The two X-linked hemorrhagic diseases hemophilia A and hemophilia B have made an important contribution to the understanding of human genetics. The first historical record of the inheritance of a disease and of "genetics"-motivated advice relates to these diseases, as do the first description of the X-linked pattern of inheritance, the appreciation of equilibria between selection and mutation, and the first attempt to estimate mutation rates. In modern times, the hemophilias have clearly illustrated the successes and problems of replacement therapy and have provided some insight into the causes of immunological complication associated with the therapeutic administration of the missing gene products. It is therefore not surprising that nowadays they attract the attention of scientists and clinicians involved in the development of gene therapy. The hemophilias, which affect 1/5000 males in the population, are members of a large group of diseases characterized by very high mutational heterogeneity. This group is of particular importance because, on the one hand, the wealth of natural mutants that each member possesses allows accumulation of detailed information on the structural features that are important to the functions of the gene and gene product involved in the disease; on the other, this creates the least favorable situation for the development of fully efficient strategies for the provision of the carrier and prenatal diagnoses that are necessary for genetic counseling. Surprisingly, mutation analysis in hemophilia A has revealed that homologous intranemic recombination between duplicated sequences can represent an important cause of recurring gene inactivation.

1 Genetics of the Hemophilias

A clear reference to the X-linked diseases, now called *hemophilias*, is found in the Babylonian Talmud of the fifth century A.D., wherein the Rabbi advises mothers who had lost two sons as a result of uncontrolled bleeding after circumcision not to expose other sons to such a risk. Furthermore, the X-linked recessive pattern of inheritance of these diseases, characterized by affected males and unaffected females who transmit the disorder, was lucidly described in 1803, more than a century before the discovery of sex-linked inheritance and 50 years ahead of Mendel's work. In 1935, it was realized that the loss of hemophilia genes due to the affected males' low probability of reproduction would have led to the elimination of the disease if an equilibrium had not existed between such loss and the gain of hemophilia genes by new mutations. Under such an equilibrium, the rate of renewal of hemophilia genes in the population is $1/3\ (1-f)$ per generation, where f is the effective fertility or genetic fitness of the affected male and 1/3 expresses the well-known fact that males account for one-third of the X-linked genes in the population, as they have only one X chromosome, whereas females have two. In 1947, investigation of the linkage between hemophilia and color blindness (another X-linked trait) offered the first hint that hemophilia was not a single disease, because while most families showed close linkage between hemophilia and color blindness, one did not. Five years later, however, the existence of two forms

of hemophilia was clearly demonstrated by complementation of the coagulation defect in a mixture of plasma from different hemophiliacs. Now, we know that deficiency of coagulation factor VIII (FVIII) causes hemophilia A, while deficiency of factor IX (FIX) causes hemophilia B and that the identical clinical features of these diseases are entirely to be expected, since FIX and FVIII are respectively the enzyme and cofactor of a functional unit that contributes to the proteolytic cascade, which converts fibrinogen into fibrin by activating coagulation factor X (Fig. 1).

Hemophilia A is 5 to 6 times more frequent than hemophilia B and, currently, in the United Kingdom, it has an incidence of approximately 1/5000 males. Until the introduction of modern therapy, the effective fertility of patients with hemophilia A or B was half that of normal individuals and, therefore, the rate of renewal of the pool of hemophilia A and B genes in the population was 1/6 per generation. This is in keeping with the clinical heterogeneity of the diseases. Since hemophilia A is 5 to 6 times more frequent than hemophilia B, and the rate of renewal of hemophilia A and B genes is similar, it follows that the rate of mutation for hemophilia A is about 5 to 6 times greater than that for hemophilia B. Indirect estimates of mutation rates in hemophilia have been based on the equilibrium postulated above, but recently, a direct estimate independent of the postulate was made in hemophilia B, through the study of the UK population, and this gave a value of 7.7×10^{-6} mutations per gene per generation, with a 95% confidence interval of 6.2 to 9.1. However, the mutation rate is higher in the male than in the female germline as the estimate of the former is 18.8×10^{-6} and that of the latter is 2.18×10^{-6} so that the ratio

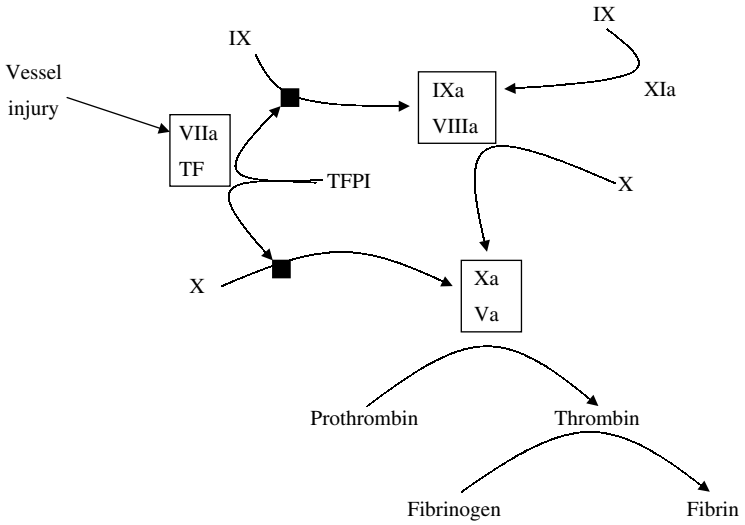

Fig. 1 The role of FVIII and FIX in blood coagulation. After tissue damage, activated FVII (FVIIa) in complex with tissue factor (TF) activates both FIX and FX, and, in turn, activated FX (FXa) and thrombin activate FVIII (not shown). Inhibition of the FVIIa–TF complex by TFPI makes further conversion of FIX to its active form dependent on FXIa and activation of FX on the FVIIIa–FIXa complex.

of male to female mutation rates is 8.64, with a 95% confidence interval of 5.46 to 14.5. This high ratio is in keeping with the theory of male-driven evolution and may be explained by the different development and physiology of the male and female gonads. Extrapolation from these data led to the suggestion that the deleterious mutation rate in the human genome is greater than 1 and possibly as great as 4 per zygote per generation. This is important because such a high mutational load in turn suggests that the long-term survival of humans depends on genetic recombination and, hence, sexual reproduction, which allows the elimination of chromosome regions carrying deleterious mutations by a process of truncating selection. This is a process that allows the elimination of mutations in bunches by preferentially eliminating zygotes with multiple deleterious mutations. In this way, it can prevent the decline in genetic fitness from generation to generation that could follow deleterious mutation rates as high as suggested above.

1.1 The Factor VIII Gene and its Product

The FVIII gene (*F8*) is 186-kb long (Fig. 2) and contains 26 exons ranging in size from 69 to 3106 bp. The latter is an internal exon (number 14) and as such is of exceptional size. The introns also vary considerably in size, from 200 bp (intron 17) to 32.4 kb (intron 22). The latter intron is of particular interest because it contains a CpG island associated with two additional RNA transcripts, one of opposite polarity to the FVIII transcript, entirely contained within intron 22 and defining an intronless gene, *F8A*, of about 2 kb and one of the same polarity as FVIII, *F8B*. This contains a first exon derived from intron 22 that contributes eight

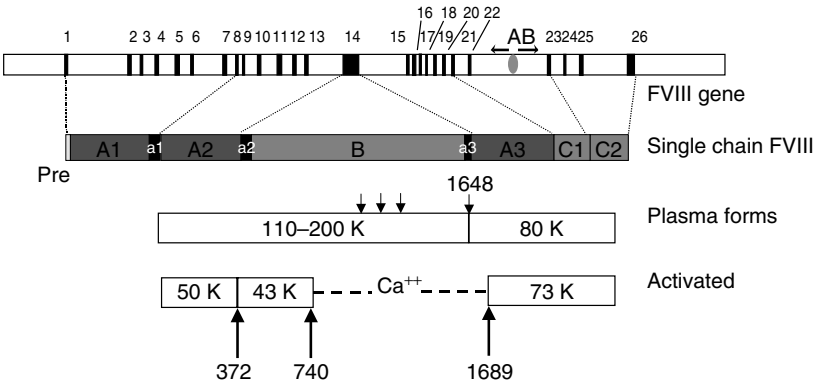

Fig. 2 Factor VIII gene (*F8*) and protein. Diagram of *F8* gene (top bar) and FVIII (lower bars). Exons are indicated by black boxes and numbered (1–26). Arrows in opposite directions over intron 22 indicate the presence of CpG island (green box) associated with the start of two transcripts of opposite orientation (A, B). Dotted lines indicate exons coding for the different protein domains (see text). Arrows in plasma and activated forms indicate site of proteolytic cleavages (see text) and numbers associated with arrows indicate position of amino acid at the amino terminal end of cleavage sites. Numbers in bars are weight in Daltons of individual protein segments. (See color plate p. xxiv.)

codons to a message comprising exons 23 to 26 of the *F8* gene. The functional significance of these two transcripts is still uncertain. A protein encoded by *F8B* has not been found yet, while the protein encoded by *F8A* has been found associated to Huntingtin. The above CpG island in intron 22 and the *F8A* gene are part of a 9.5-kb sequence called *int22h* that is repeated 500 and 600 kb more telomerically.

The FVIII mRNA is thought to be 9028-nt long with a 170 leader sequence followed by 2351 codons and an 1805-nt untranslated 3′ tail. The primary translation product starts with a prepeptide of 19 residues needed for intracellular transport and secretion. The remainder of the protein consists of six domains and three small acidic peptides (a_1 to a_3) arranged as follows: $A_1a_1A_2a_2Ba_3A_3C_1C_2$. The A domains consist of approximately 330 amino acids (aa) and are homologous to ceruloplasmin. The B domain (encoded by exon 14) contains 983 aa and is unique. The C domains consist of approximately 150 aa and are homologous to a recently described milk fat globule binding protein and the slime mold's discoidin. Factor V, the cofactor of factor X that is responsible for the activation of prothrombin, is a homolog of FVIII and has a similar protein domain structure; however, it lacks the three acidic peptides (a_1, a_2, and a_3) and has a B domain with no homology to that of FVIII.

The FVIII polypeptide undergoes extensive intracellular modification including glysosylation, sulfation, and proteolytic cleavage. Glycosylation is both O and N linked, and FVIII contains 26 glycosylatable asparagines of which 19 are in the B domain. Sulfation is known to occur at the following tyrosines: Tyr_{346}, Tyr_{718}, Tyr_{719}, Tyr_{723}, Tyr_{1664}, and Tyr_{1680}. Secretion of FVIII requires not only post translational glycosylation of the asparagines in the B domain but also processing of the glycosidic chains to fully glucose-trimmed mannose 9 structures. The transfer of FVIII from the endoplasmic reticulum to the Golgi apparatus is achieved with the intervention of trafficking factors, as revealed by the fact that absence of endoplasmic reticulum Golgi intermediate compartment -53, or ERGIC-53 for short, causes combined deficiency of both FVIII and FV.

Prior to secretion, FVIII is cleaved not only to release the prepeptide but also at the B/a_3 boundary (aa 1648–1649) to form a molecule with a light chain consisting of $a_3A_3C_1C_2$ (aa 1649–2232) and a heavy chain consisting of $A_1a_1A_2a_2B$. This chain, however, is of variable length since the B domain is also cleaved at variable internal positions.

Circulating FVIII is bound to and protected by the von Willebrand factor (vWF). Two FVIII regions are important for this binding: the a_3 peptide and in particular the sulfated tyrosine at position 1680 within this peptide and a region at the carboxyl end of the C_2 domain comprising residues 2303–2332. Conversion of FVIII to its active form entails cleavage at the a_1/A_2 and the a_3/A_3 boundaries (aa Arg_{372}-Ser_{373} and Arg_{1689}-Ser_{1690}). The former cleavage transforms factor VIII into a three-chain molecule and the latter releases factor VIII from von Willebrand factor. Activation is also accompanied by cleavage at the a_2/B boundary. The activated FVIII is relatively unstable and, in particular, the dissociation of the A_2 domain from the active heterotrimer results in loss of activity. Activated protein C, an important regulator of coagulation, cleaves FVIII at the A_1/a_1 boundary (Arg_{336}-Met_{337}) and causes its inactivation, but this protein also cleaves at Arg_{562}

and this may represent an important target for inactivation by protein C. In addition, work on the clearance of FVIII from the circulation has suggested that in the absence of vWF binding FVIII is rapidly cleared by a process that involves a member of the family of endocytic receptors: the low-density lipoprotein receptor–related protein also called the *α_2-macroglobulin receptor*.

The large size and multiple forms of the FVIII protein in circulation have hindered crystallographic investigation, but a model of the tridimensional structure of the A domains of FVIII has been derived, by analogy, from the crystal structure of ceruloplasmin. Crystals of the C_2 domain of FVIII have provided data on the tridimensional structure of this module and, finally, two-dimensional analysis of crystals formed by activated FVIII in association with phospholipidic membranes has yielded a picture of the arrangement of the activated FVIII domains relative to each other, the phospholipidic membrane and activated FIX.

The C_2 domain essentially consists of an eight-stranded antiparallel β-barrel formed by two β-sheets tightly packed against each other. Loops projecting from one end of the barrel have been shown to be important for the binding to phospholipidic membranes. Thus, it appears that three hydrophobic feet formed by the side chains of Met_{2199} and Phe_{2220}, Val_{2223} and Leu_{2251} plus Leu_{2252} embed into the membrane, while the four basic residues Arg_{2215}, Arg_{2220}, Lys_{2227}, and Lys_{2249} interact with the negative charges of the phospholipids.

The C_1 domain of FVIII can be modeled on the C_2 domain, especially in the core regions that are more conserved. The model of the three A domains of the activated FVIII suggests that these domains are arranged in a triangular structure, while the two-dimensional crystals of activated FVIII prepared on monolayers of negatively charged phospholipids indicate that the C_2 domain penetrates the membrane with four loops. The C_1 domain is almost at a right angle to C_2 and has its major axis parallel to the membrane. The A_3 domain is in close association with the C_1 and C_2 domains near the membrane, and the heterotrimer of A domains is tilted approximately 65° relative to the membrane plane, with the A_2 domain protruding partially between the A_1 and A_3 domains.

1.2 The Factor IX Gene and its Product

The FIX gene (*F9*) is approximately 33-kb long (Fig. 3) and contains eight exons varying in size from 25 to 1935 bp. The introns also vary in size from 188 to 9473 bp. The gene promoter has been partly characterized and binding sites for a number of transcription factors (NF1-L, androgen receptor, LF-A1/HNF4, DBP, and members of the C/EBP family) have been found close to the transcription start site. The FIX mRNA is 2802-nt long and includes a leader sequence 29- to 50-nt long, depending on the true position of the translation start, and 1390 nt of 3′ untranslated tail. There is a close correspondence between *F9* exons and protein domains. These are modules shared by large families of proteins, and the structure of the *F9* gene is consistent with the exon-shuffling hypothesis of gene evolution. Three other proteins of blood coagulation are coded by genes with the same structure as *F9*, that is, factors VII, X, and protein C. These genes are probably derived from the same ancestral gene as FIX. More remotely related to *F9* gene is the prothrombin gene, as these two genes

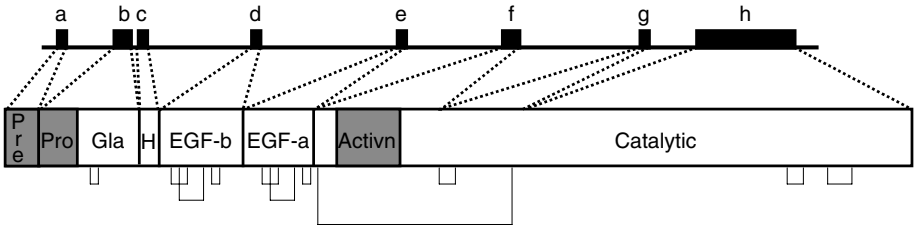

Fig. 3 Factor IX gene (*F9*) and protein. Diagram of *F9* gene (upper line) and FIX (lower bar). Exons are indicated by black boxes and labeled (a–h). Dotted lines show domains encoded by individual exons. Green areas are protein domains cleaved prior to secretion (pre, pro) or at activation: pre = prepeptide; pro = propeptide; gla = gla region; H = hydrophobic stack; EGF-b = first epidermal growth factor domain with Ca^{++} binding site; EGF-a = second epidermal growth factor domain; activn = activation peptide flanked by carboxyl end of light chain of activated factor IX and amino end of the catalytic region. Disulfide bridges in factor IX are shown below the protein domains. (See color plate p. xxiv.)

show identical arrangements only for the first three exons and are homologous only in this region and in that encoding the catalytic domain.

The first exon of *F9* codes for the predomain of the leader peptide that is involved in the transport and secretion of FIX. The second exon codes for the prodomain of the leader peptide and the gla region. These two domains are functionally related since the propeptide binds the enzyme responsible for the γ-carboxylation of 11 glutamic acid residues that give the name to the gla region (γ-carboxyglutamic acid = gla). The third exon codes for a small hydrophobic region that contains the 12th gla residue of FIX. The gla region confers on FIX affinity for phospholipidic membranes. The fourth and fifth exons code for domains homologous to epidermal growth factor (EGF domains). The first of these domains is called *type B* and contains a high-affinity Ca^{++} binding site contributed by Asp_{47}, Asp_{49}, Gln_{50}, and Asp_{64}. The latter residue also undergoes β-hydroxylation in a proportion of the FIX molecules while Ser_{53} and Ser_{61} are glycosylated. The second EGF domain that lacks the Ca^{++} binding site and β-hydroxylated residue is called *type A*. The EGF domains are involved in protein–protein interaction. Thus, the gla plus the EGF1 domain of FIX seems to interact with the activated FVII and tissue factor complex that activates FIX and the interface between the two EGF domains with residues 1811–1818 of FVIII. The sixth exon codes for the activation domain that comprises a peptide of 35 aa (residues 146 to 180) that is cleaved off during activation. This contains two glycosylated asparagines (Asn_{157} and Asn_{167}). Finally, the last two exons of the *F9* gene code for a catalytic domain that has all the features of serine proteases (e.g. trypsin). Thus, His_{221}, Asp_{269}, and Ser_{365} are considered the cardinal residues of the active center and Asp_{359} the residue conferring affinity for basic residues. Residues 301–303 and 333–339 of FIX appear to interact with residues 558–565 and 698–712 of the A_2 domain of activated FVIII.

FIX is synthesized in the liver as a precursor molecule with a leader peptide of 46, 41, or 39 aa; it is not known which of these is correct, but 39 is probable. This peptide is cleaved prior to secretion in two independent steps for the pre- and prodomains. Circulating FIX is a

monomer of 415 aa that upon activation by FXI or FVII plus tissue factor is converted into a two-chain molecule.

Crystallographic and other structural studies have shown that the gla domain that contains the phospholipids binding site has at the N terminus a tightly hydrogen-bonded complex involving two calcium ions and a pseudoplanar network of six to seven calcium ions that are tightly associated with gla residues. A helix then connects the calcium-associated fragment to the EGF1 domain. The calcium ion bound to the EGF1 domain is presumed to fit in the interface between the gla and EGF1 domain. The principal axes of the oblong EGF domains form an angle of 100° stabilized by an interdomain salt bridge. The catalytic region is localized above the EGF2 domain so that the activated FIX molecule shows a curved configuration with the catalytic center about 80 Å above the phospholipidic membrane surface. The concave surface of activated FIX contains interacting sites for FVIII and sites affected by hemophilia B–causing mutations.

2 Hemophilia A Mutations

The large size and complexity of the *F8* gene has meant that adequate screening of this gene for hemophilia A mutations has had to wait for the development of novel, efficient, and fast methods. Of particular value in this respect was the use of traces of FVIII mRNA in the RNA prepared from peripheral lymphocytes. This, in particular, has revealed that 20% of all cases and 50% of those with severe hemophilia are due to gross unexpected disruptions of the *F8* gene. The other hemophilia A mutations are mostly small changes that involve single base substitutions or the insertion and deletion of a few nucleotides, while gross deletions or duplications are relatively rare (Fig. 4).

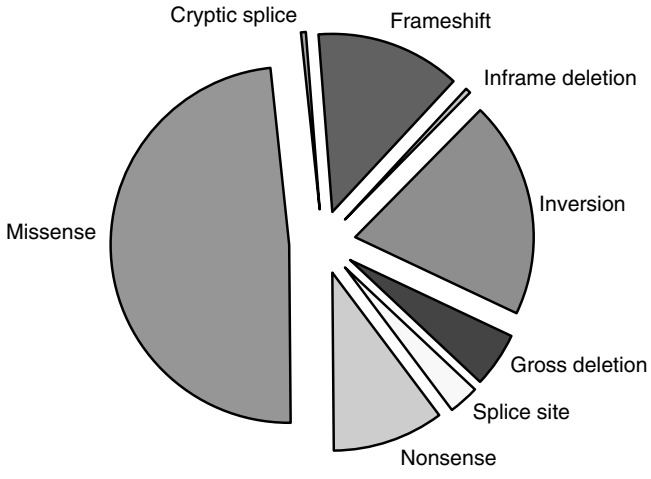

Fig. 4 Pie chart showing the different types of mutations reported in hemophilia A. Cryptic splice refers to mutations generating novel splice signals. In-frame deletion refers to mutations causing loss of one or more codons.

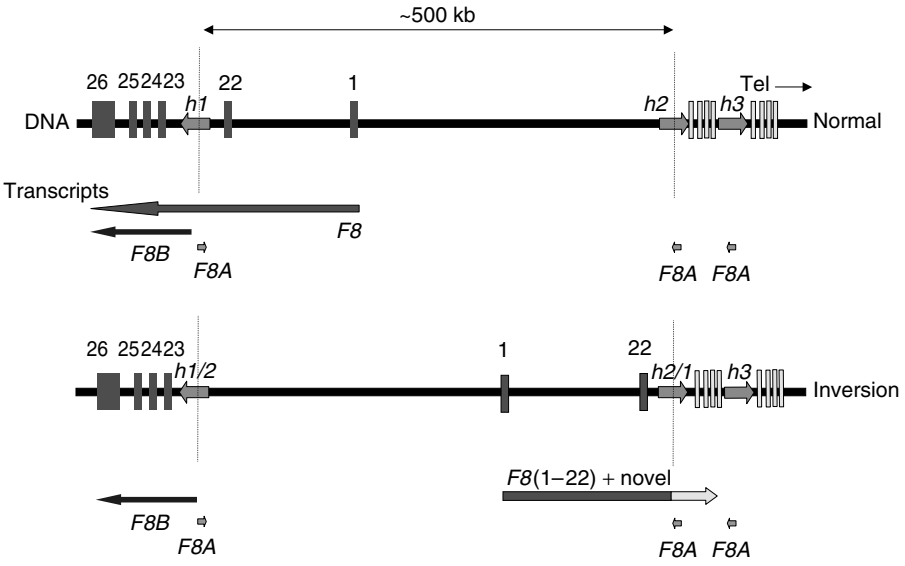
2.1
Gross Sequence Changes

In the United Kingdom, the study of 25% of the hemophilia A population has shown that 1.2% of patients have gross gene deletions. The world database of hemophilia A mutations (HAMSTeRS at http://europium.csc.mrc.ac.uk) records 116 gross deletions. These may involve the whole or a part of the gene (e.g. a single exon), and are usually associated with severe disease. In this series, the four deletions that are accompanied by moderate hemophilia affect exons 5 and 6; exon 22; exons 23 and 24; and exon 25. The mRNA in these cases is expected to maintain the normal reading frame and, presumably, the deletion simply leads to the loss of the aa encoded by the missing exons.

Large insertions are quite rare, but two interesting patients have been reported with insertion of the repetitive LINE sequence in AT-rich regions of exon 14. These have been shown to be recent transposition events from an active LINE sequence in chromosome 22.

The major cause of gross *F8* gene rearrangements is inversions. These, as mentioned above, cause 50% of the instances of severe hemophilia A or about 20% of all cases of the disease. Two main types of inversion exist: one that breaks the *F8* gene in intron 22 and one that breaks intron 1. The former accounts for 45% and the latter for 5% of patients with severe hemophilia A.

The inversions breaking intron 22 (Fig. 5) were the first to be discovered, and formal proof was obtained that the inversions result from intranemic homologous recombination between repeats of a 9.5- kb sequence called *int22h*. One copy of this sequence (*int22h-1*) is part of intron 22 of the *F8* gene, while a second (*int22h-2*) and third copy (*int22h-3*) are respectively located 500 and 600 kb more telomerically and are both in inverted orientation relative to *int22h-1*. These repeats are more than



99.9% identical. Inversions due to homologous recombination between *int22h-1* and *int22h-3* are 5 to 6 times more common than those involving *int22h-1* and *int22h-2*, but the reason for this bias is unknown. It also appears that these inversions arise predominantly during male gametogenesis. Since the above inversions cause severe disease and hence are under strong negative or purifying selection, their high frequency is explained by a high rate of mutation. Estimates of 4 and 7×10^{-6} *int22h*-related inversions per gamete per generation have been offered. The *int22h*-related inversions are the first mutations sought in patients with severe hemophilia A, and this is done either by Southern blotting or by a more rapid PCR-based procedure.

The inversions breaking intron 1 of *F8* (Fig. 6) arise by intranemic homologous recombination like the *int22h*-related inversions. The sequence involved in this recombination is a 1041-bp segment of intron 1 called *int1h-1* that is duplicated in inverted orientation 140 kb more telomerically to yield *int1h-2*. These two repeats are more than 99.9% identical.

The *int1h*-related inversions are about ninefold rarer than the *int22h*-related inversions, and this reflects the size difference between the *int1h* and *int22h* repeats, in keeping with the idea that the frequency of homologous recombination is related to the length and degree of identity of the sequences involved.

2.2 Small Sequence Changes

A variety of small sequence changes has been reported, but none so far affecting the putative *F8* promoter. The known mutations, therefore, may primarily affect RNA processing, translation, or the fine structure of FVIII.

2.2.1 Changes Affecting RNA Processing

The presence of traces of FVIII mRNA in peripheral lymphocytes offers the opportunity to detect mutations altering the structure of mRNA irrespective of where they are located within the *F8* gene or, indeed, to confirm that mutations postulated to alter mRNA processing actually do so. Many of these mutations can be expected to alter the donor or acceptor splice signal with consequent skipping of the affected exon. In some patients, however, alteration of the normal splice signal is accompanied by the activation of cryptic splice signals in the affected exon or in the adjacent intron, thus respectively causing partial exon exclusion and exon extension. Finally, more rarely, patients are found to

Fig. 5 Diagram of *int22h*-related inversion, showing its transcriptional consequences. Top: normal structure of DNA region and *F8* gene transcripts (not drawn to scale). *F8* = transcript encoding coagulant factor, *F8A* and *F8B* = transcripts arising from CpG island in *int22h* repeat. Green arrows in genomic DNA represent *int22h* repeats (*h*1 = *int22h*-1, *h*2 = *int22h*-2, *h* = *int22h*-3). Red bars indicate some numbered exons of the *F8* gene, yellow bars are exons unrelated to the *F8* gene. Vertical dotted lines are sites where intranemic homologous recombination occurs and leads to the inversion. Tel → shows direction to telomere. Arrow point in transcripts indicates 3′ end. Bottom: structure of DNA region with inversion resulting from recombination of *int22h*-1 with *int22h*-2. *H1/2* and *h2/1* are the recombined *int22h* repeats. The transcripts show that the *F8* transcript contains only exons 1 to 22 of *F8* attached to the normally unrelated yellow exons and that exons 23 to 26 are present only in the *F8B* transcript. NB inversions involving *int22h*-3 yield analogous transcripts. (See color plate p. xxiii.)

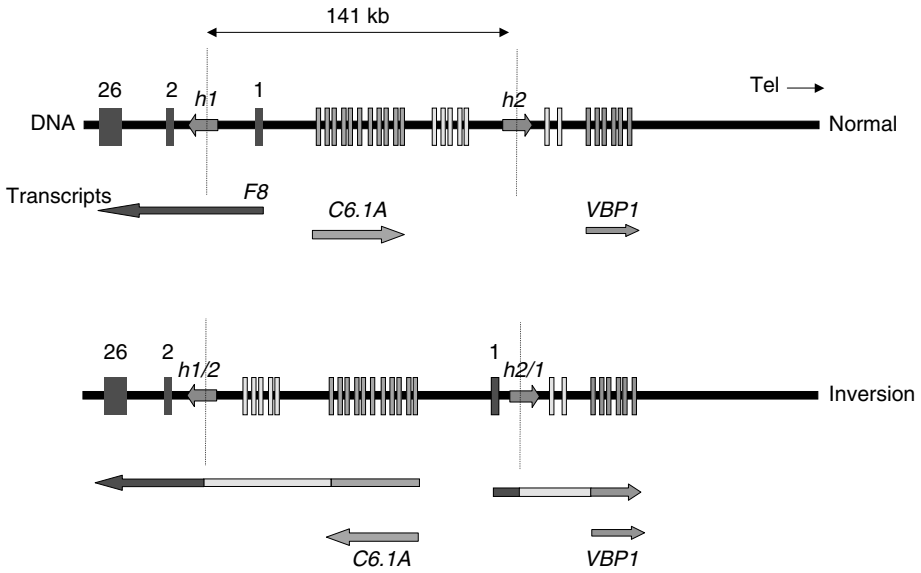


Fig. 6 Diagram of *int1h*-related inversion, showing its transcriptional consequences. Top: normal structure of DNA region and relevant transcripts (not drawn to scale). Red bars indicate numbered exons of *F8*. Light green and blue bars are exons of the *C6.1A* and *VBP1* gene respectively; yellow bars are exons unrelated to the above three genes. Green arrows in DNA are *int1h*-1 (*h1*) and *int1h*-2 (*h2*). Vertical dotted lines indicate sites where intranemic homologous recombination occurs and leads to inversion. Arrow point in transcripts indicates 3′ end. Bottom: structure of DNA region with inversion and relevant transcripts. *H1/2* and *h2/1* are recombined *int1h* repeats. Transcripts show that *F8* contributes to two mRNAs: one containing all but the last exon of *C6.1A*, some novel exons and exons 2 to 26 of *F8* and one containing exon 1 of *F8* plus novel exons and all but the first exon of *VBP1*. The patients' cells also produce normal *C6.1A* and *VBP1* mRNA. (See color plate p. xxv.)

produce mRNA with an additional exon because of single base substitutions generating a novel splice signal in a region of an intron close enough to a cryptic splice signal appropriate to the definition of a novel exon.

The severity of the disease in patients with the above mutations appears to be related to whether a fraction of the pre-mRNA can be spliced into wild-type molecules or whether the abnormal mRNA has retained a normal reading frame. When the normal reading frame has been lost and no normally spliced mRNA is produced, the patient tends to have severe hemophilia A.

2.2.2 Changes Affecting mRNA Translation

HAMSTeRS lists nonsense mutations at 95 different codons, and at 12 of these sites, the mutations were transitions at a CpG dinucleotide. These are usually observed in multiple patients because of the relatively high rate of transition mutations at this type of dinucleotide.

Nonsense mutations should result in premature termination of translation and hence in truncated FVIII, which may or may not be stable enough to be secreted. However, a phenomenon called *nonsense mediated mRNA degradation* may lead to mRNA instability and hence

prevent or grossly reduce FVIII synthesis. Conversely, some nonsense mutations may also impair exon recognition and splicing. In this case, exon skipping may restore the reading frame in at least some mRNA molecules, which can then be expected to produce FVIII lacking the amino acids encoded by the exon that has been skipped.

Nonsense mutations are fairly evenly distributed along the FVIII coding sequence and are generally associated with severe hemophilia A.

HAMSTeRS lists small deletions causing frameshifts at 138 sites and small insertions also causing frameshifts at 48 sites of the FVIII coding sequence. At most of these sites, the mutations appear to be unique events but there are some sites that are repeatedly affected and thus represent hotspots of deletion or insertion. The most spectacular hotspots are represented by regions of single base repeats such as strings of A that are present at various locations in exon 14. These appear to undergo slippage during DNA replication, thus acquiring or losing a base. High mutation rates at mononucleotide repeats could lead to somatic mosaicism in the patient with reversion of the mutation, and this would have beneficial effects. Alternatively, errors occurring during transcription could result in some mRNA molecules with a restored reading frame. It is interesting, therefore, to note that while patients with frameshift mutations usually have severe disease, a few with mild or moderate disease have been listed and these bear frameshifts affecting polyA strings. In the absence of the above corrections, occurring either in some cells at DNA replication or in some transcripts during gene expression, frameshifts tend to cause functional defects similar, by and large, to gross deletions and nonsense mutations.

2.2.3 Mutations Causing Alterations of the Fine Structure of Factor VIII

HAMSTeRS contains two mutations resulting in amino acid addition: Ile at codon 613 in one case and a string of six amino acids after residue 1888 in the other. Conversely, the database contains eight amino acid deletions, of which five affect a single residue, two affect two residues, and one affects four residues. However, the mutations that affect the fine structure of FVIII are mostly amino acid substitutions. The above database, after exclusion of the UK patients studied in the course of establishing a confidential national database of hemophilia A mutations and pedigrees, contains 437 different missense mutations, 324 of which are unique events while 113 have been observed two or more times. The above UK study has examined 767 unrelated patients and can be contrasted with the data summarized in HAMSTeRS in order to estimate the total number of FVIII missense mutations that can cause hemophilia A. The 437 missense mutations in HAMSTeRS represent the group of missense mutations causing hemophilia A that is already known. The size of the group formed by hemophilia A missense mutations that are still unknown can be estimated if the missense mutations found in the UK sample are divided into those that are listed in HAMSTeRS and those that are not. The ratio of the latter to the former is proportional to the number of different missense mutations that can cause hemophilia A and are not found in HAMSTeRS. In fact, 102 of 202 missense mutations found in the UK study are novel relative to HAMSTeRS and, hence, the missense mutations causing hemophilia A and yet not in this collection should be 221 (i.e. $102/202 \times 437$), so that the total number of missense mutations capable of causing

hemophilia A can be assumed to be about $221 + 437 = 658$. This is not a particularly high figure if one considers that the *F8* gene encodes 2351 amino acids and that 15,588 missense mutations can occur in this gene.

The distribution of missense mutations causing hemophilia A is far from being homogeneous (Fig. 7). Thus, the B domain is bereft of such mutations while it has a proper share of nonsense mutations and even an excess of frameshift mutations. This is explained by the fact that the B domain does not contribute to the coagulant activity and hence to the antihemophilic function of FVIII.

The three A domains of the patients' FVIII show similar numbers of missense mutations and these preferentially appear to occur at residues that are identical in the three A domains, as the known mutations affect 44% of these residues while they involve only 28% and 24% of those that are, respectively, identical in only two domains or different in all three domains. Similarly, the known missense mutations in the C domains affect 42% of the residues that are identical in all the C domains of both factor VIII and factor V, while they affect only 22% of the residues that are identical in the C domains of factor VIII and 11% of the residues that are not identical in the C domain of factor VIII.

These data indicate that substitution of residues important for the basic structure of the A and C domains are much more likely to cause hemophilia A than substitution of other amino acids.

A number of missense mutations affect residues of known functional importance. Thus, Arg has been found to be substituted for Ser_1 at the cleavage site of the prepeptide. Pro, His, or Cys, and Pro or Leu, respectively, have been found substituted for Arg_{372} and Ser_{373}, which form an activation cleavage site. Similarly, Cys or His, and His or Arg, respectively, have been found substituted for Arg_{1689} and Ser_{1690}, which also form an activation cleavage site.

Conversely, some missense mutations have indicated residues important to the stability of the FVIIIa heterotrimer because they affect the interfaces between the A_1/A_2, A_1/A_3, and A_2/A_3 domains. This group of mutations includes the following: R284E, R284P, S289L, R527W, R531H, R531G, Q694I, R698L, R698W, L1932F, M1947I, G1948D, and H1954L. Interestingly, coagulant assays on patients with these mutations show higher values when they include FVIII activation in

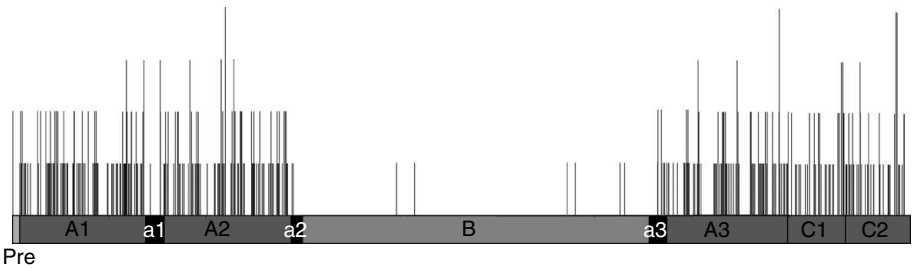

Fig. 7 Missense mutations of *F8* associated with hemophilia A. The horizontal bar shows the domains of the FVIII polypeptide. The vertical lines show the positions of missense mutations, and their heights are proportional to the number of different substitutions (from 1 to 4) found at each residue. Any line thicker than the minimum thickness indicates mutations at two or more residues close to one another but not necessarily adjacent in FVIII (data from HAMSTeRS).

the measuring phase (1-stage assays) than when FVIII activation is allowed to precede the measuring phase (2-stage assays) as this is likely to allow greater FVIII inactivation, prior to measurement, if the FVIIIa heterotrimer is unstable. *Ad hoc* experiments for some of these mutations have demonstrated abnormally rapid dissociation of the A_2 domain from the heterotrimer.

Missense mutations in hemophilia A may also offer some information on the importance of sites of protein interaction. Three regions of FVIII are considered binding sites for FIX: residues 558–565, 698–712, and 1811–1818. The first two interact respectively with the region of FIX residues 333–339 and 301–303; the third appears to interact with the interface between the two EGF domains of FIX. In HAMSTeRS, eight missense mutations are listed for the first site, nine for the second, and none for the third. With regard to the interaction of FVIII with vWF, the Y1680C and Y1680F mutations found in hemophilia A patients bear witness to the importance of this sulfated tyrosine for the binding to vWF. Fifteen different missense mutations affecting the binding of FVIII to vWF have been found in the C domains.

2.3 Functional Interpretation of Observed Sequence Changes and Correlations between Genotype and Phenotype

A proportion of the observed FVIII mutations can undoubtedly be considered detrimental, that is, gross deletions or other gross rearrangements involving the essential sequences of the gene, such as the *int22h*- and *int1h*-related inversions, alteration of absolutely conserved elements of the splice site consensuses, frameshifts, and nonsense mutations. However, the accurate prediction of the functional consequences of mutations detected in genomic DNA may demand mRNA analysis.

Many mutations are not overtly detrimental and do not lead to gross mRNA aberrations. In order to determine the detrimental nature of such mutations, it is important to have accurate diagnoses and to perform a very thorough mutation screen on the *F8* gene. In particular, one should exclude diseases that can mimic hemophilia A. At present, we know of two such conditions: the combined deficiency of FV and FVIII associated with defects in secretion pathways and the Normandy-type von Willebrand disease due to mutations that impair the ability of vWF to bind FVIII. Mutation screening of the *F8* gene should ensure levels of detection as close as possible to 100%. Currently, this can be done best by procedures that include the use of mRNA. Under these conditions, mutations that represent the only change detected in the *F8* gene are likely to be the cause of the disease. In some cases, family studies can show that the mutation found in a patient is of recent origin and this strongly supports its deleterious nature. Also, the independent occurrence of the same mutation in two or more patients strongly supports the idea that the mutation is the cause of the disease. Less useful indicators of the disease-causing role of observed sequence changes are considerations on the degree of conservation of the mutated residues of FVIII or the chemical difference between the normal and the mutant FVIII residues. The accumulation of thorough hemophilia A mutation data should also help identify neutral polymorphisms, as these may appear as second changes common to patients with different disease-causing mutations.

With regard to the correlation between phenotype and genotype, missense mutations are frequently associated with mild or moderate disease.

Variability in the severity of the disease has been reported among hemophilia A patients with the same mutation, and this may be due to polymorphic variation in genes that encode factors important for the maturation, secretion, transport, clearance, and modulation of the activities of FVIII.

The most worrying phenotypic feature of patients with hemophilia A is the propensity to develop antibodies against therapeutic FVIII. The risk of developing such antibodies or inhibitors is strongly correlated with the type of mutation causing the disease. Thus, a risk of about 30% is associated with the *int22h*-related inversions, gross deletions, and nonsense mutations, while frameshifts show a lower risk of about 20% and missense mutations an overall risk of 8%. HAMSTeRS shows 39 missense mutations associated with the presence of inhibitors and for 20 of these mutations, there are two or more patients per mutations with information on the inhibitor status, forming a total of 161 patients, 48 of which (29.8%) had inhibitors. This suggests that most of the risk of inhibitors associated with missense mutations is due to a small group of residues and their substituents that possibly create novel antigenic epitopes. Some evidence that this might be the case has been obtained for inhibitors associated with the mutations R593C and R2150H. With regard to the first mutation, a patient has been reported with inhibitors directed exclusively against the wild-type FVIII, while, with regard to the second mutation, two patients with high titer inhibitors were reported who still displayed significant levels of FVIII activity, thus suggesting that the patients' mutant FVIII was not recognized and hence not blocked by the patients' inhibitors. The high risk of inhibitors associated with gross rearrangements and nonsense and frameshift mutations is best explained by the inability of patients with these mutations to produce FVIII. This could result in lack of immunological tolerance to FVIII, which would not be recognized as "self." As nonsense and frameshift mutations are expected to cause similar effects on FVIII synthesis, the reasons why frameshifts are associated with a somewhat lower risk of inhibitors should be considered. The insertion or deletion mutants in polyA regions ($\geq$6A residues) appear to be mainly responsible as they show a very low risk of inhibitors. Thus, only five (6.5%) of 76 patients with these frameshifts are reported as having inhibitors in HAMSTeRS. Possibly, this is due to errors of replication or transcription of the mutated polyA regions, which, as mentioned above, may allow production of traces of FVIII that may serve to develop immune tolerance to FVIII.

3 Hemophilia B Mutations

The vast majority of hemophilia B mutations are due to single base-pair substitution, or deletion and insertion of a few base pairs, while gross deletions and other rearrangements are rare (Fig. 8). So far, 2847 mutations involving small sequence changes and 90 gross deletions have been reported in the world database (http://www.kcl.ac.uk/ip/petergreen/haemBdatabase.html). However, large population samples provide more precise information on the relative frequency of gross and small sequence changes.

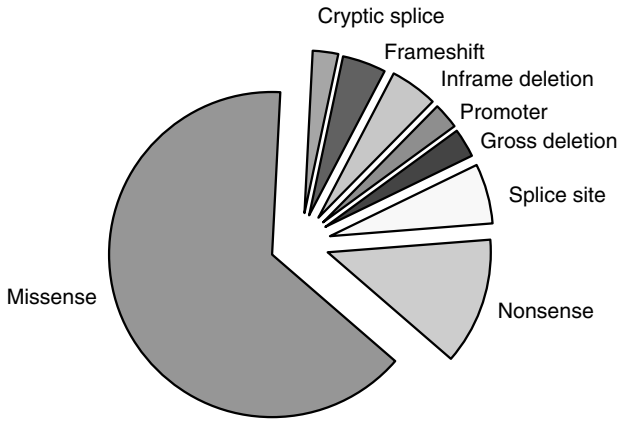

Fig. 8 Pie chart showing the different types of mutations reported in hemophilia B. Promoter refers to mutations affecting the *F9* promoter.

3.1 Gross Sequence Changes

A fairly unbiased sample representing >70% of the UK hemophilia B population has shown that gross sequence changes account for about 1.5% of the patients. Most gross mutations are deletions that may involve the whole or part of the *F9* gene. They usually cause severe disease with no measurable FIX protein in circulation. However, in one patient, with deletion of the fourth exon (exon d), significant amounts of circulating FIX have been reported. Such a deletion should not alter the reading frame of the mRNA. Large insertions are very rare and among those of particular interest is the insertion of an Alu repeat, as it raises the issue of ongoing retrotranspositions in the human genome.

3.2 Small Sequence Changes

The 2847 hemophilia B mutations due to small sequence changes (<20 bp) consist of 2646 single base substitutions, 160 deletions, 38 insertions, and 3 combined deletions and insertions. Furthermore, 28 patients showed two, and one patient three *F9* gene mutations, probably, and in some cases certainly, representing the association of a detrimental mutation with additional "private" neutral sequence changes. Excluding such additional changes, 916 unique molecular events have been identified, while the remainder are repeats of previously observed changes. Many of these are CG > TG or CA changes that define mutational hotspots but, in some instances, frequent repeated observation may be due to founder mutations. This probably applies to some of the −6G > A promoter mutations, to the three missense mutations G60S, T296M, and I397T, and to the 17810A > G base substitution in intron 5 that creates a novel donor splice signal. This fits the consensus better than the normal site, is located 13-nt downstream of exon e and causes a mild hemophilia, accounting for 5.5% of hemophilia B patients in the United Kingdom.

3.2.1 Mutations Affecting Transcription, RNA Processing, and Translation

Detrimental promoter mutations should, by definition, impair transcription. Twenty-one different promoter mutations have been reported (Fig. 9). They affect binding sites for different transcription factors (LF.A1/HFN4, DBP, C/EBP), and usually cause a disease characterized by a clinical and hematological age-related improvement (especially postpubertally) that may lead to complete loss of symptoms. However, no age-related improvement has been reported in patients with substitution of residue −26 (G > C, G > A or G > T), which is part of a weak androgen response element (nt −36 to −22) that in its 3′ region overlaps with an LF.A1/HNF4 binding site. It seems probable that the improvement of patients with promoter mutations is due to the greater dependence of the promoter on developmentally related stimulatory events such as increases in androgen levels.

Very high amplification of nucleic acid sequences has allowed examination of tissue-specific mRNAs in tissues that do not express these mRNAs as traces of the relevant mRNA are nevertheless found. However, the *F9* gene, mainly expressed in the liver, is unusual because while trace levels of FIX mRNA are present in lung, skeletal muscle, and heart, no traces of full-length FIX mRNA are found in peripheral lymphocytes, lymphocyte-derived cell lines, or pancreas. Instead, a novel mRNA is found that contains only the last two exons of the *F9* gene. This has prevented thorough analysis of the *F9* mutations that affect mRNA processing. Nevertheless, several mutations that can be expected to affect mRNA splicing have been reported as probable causes of hemophilia B. These include base substitution or deletion of the very highly conserved dinucleotides at the start and end of each intron, alteration of less conserved elements of the splice signal and also the generation of novel splice signals such as that described in the previous section as causing 5.5% of all UK hemophilia B and a new donor splice in the 3′ untranslated tail of the message. The latter has been observed repeatedly in patients with severe disease and appears likely to disrupt the processing of the 3′ end of the message.

Mutations affecting translation, that is, frameshifts and nonsense codons, are scattered throughout the FIX coding sequence. Interestingly, these mutations, irrespective of their location, are usually associated with absence of FIX protein in circulation. Thus, even translation stops very close to the end of the protein (e.g. codon 411) have been found in patients

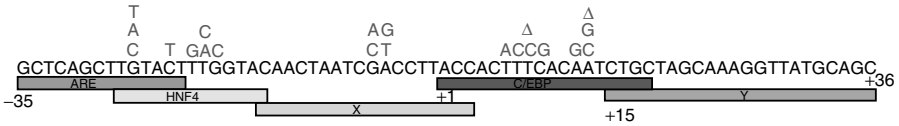

Fig. 9 Hemophilia B mutations affecting the promoter of *F9*. Mutant residues are in red, Δ indicates single base deletion. Bars below promoter sequence indicate mutation-affected regions known to bind transactivating factors. ARE = androgen responsive element, HNF4 = liver-specific transcription factor binding site, C/EBP = binding site for members of the C/EBP family of transactivating factors, X = region binding HNF4 and members of the steroid hormone receptor super family (ARP1, Coop/Ear3) that appear to exercise repressor activity on *F9* promoter. (See color plate p. xxiv.)

with no circulating FIX. This suggests that even moderately truncated FIX and/or FIX mRNA containing premature stop codons are unstable.

3.2.2 Missense Mutations and Single Amino Acid Deletions

Twelve different single aa deletions and 549 substitutions have been reported so far plus five aa substitutions that are probably or certainly neutral R-44H, I-40F, A147T, F178L, and V328I. The above 549 missense mutations affect 225 residues of FIX (Fig. 10) plus seven codons that contribute to splice consensuses. It is difficult to know whether these seven mutations mainly act by changing an amino acid in FIX or by impairing mRNA formation.

The leader peptide is relatively lightly affected and its prodomain shows mutations essentially in a region important for its cleavage from the mature protein. The Val-$_{10}$, which is important for the binding of the γ-carboxylase that modifies the gla residues, has shown two substitutions (A-10T and A-10V) that do not cause hemophilia B but are associated with hypersensitivity to warfarin, an antagonist of vitamin K, which is the cofactor of γ-carboxylase. Several residues of the gla domain are affected by mutation, including gla residues (except those at positions 15, 36, and 40) and the Cys_{18} and Cys_{23}, which form a disulfide bridge. All together 55 missense mutations have been found in this domain, which contains 38 amino acids. The EGF type B domain shows 66 different missense mutations affecting, among others, residues involved in the high affinity Ca^{++} binding site and the cysteines of the three disulfide bridges characteristic of these domains. The EGF type A domain shows a lower number of missense mutations (43), many of which affect the six cysteines involved in disulfide bridges. The activation domain shows relatively few mutations and these are concentrated in regions of obvious functional importance such as Cys_{132}, which is part of a disulfide bridge that holds together the light and heavy chain of activated FIX and its immediate neighbors; the residues of the cleavage sites necessary for the excision of the activation peptide; and the first residues of the heavy chain of activated FIX that are part of the catalytic domain. Three hundred and nine different amino acid substitutions are distributed throughout the catalytic domain, and bear witness to the fairly highly constrained nature of

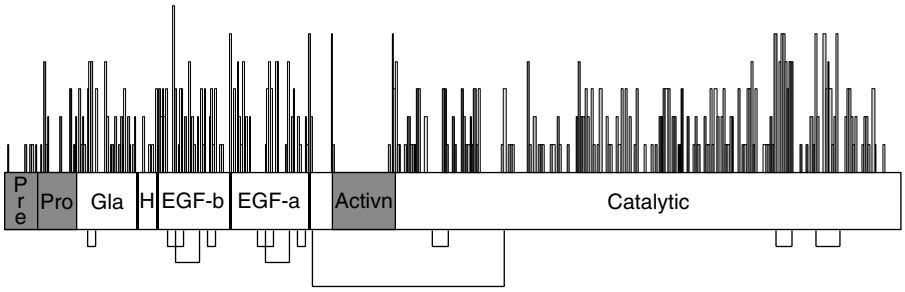

Fig. 10 Missense mutations of *F9* associated with hemophilia B. The horizontal bar shows the domains of the FIX polypeptide with its disulfide bridges indicated below. The vertical lines mark the positions of missense mutations and their heights are proportional to the number of different substitutions (from 1 to 6) found at each residue (data from http://www/kcl.ac.uk/ip/petergreen/haemBdatabase.html).

this domain. The highest concentration of missense mutations is found in the region comprising Ser_{365} of the active center and also in a region comprising residues that form the entrance to the activated FIX specificity pocket. The α-helix comprising residues 330 to 338 is also rich in missense mutations. A number of loops border the substrate-binding groove. Of these, two: (residues 199–204 and 223–229) seem mutation-poor, while the others (235–245, 256–268, 312–322, and 340–347) show average to high numbers of mutations.

In general, the missense mutations found in hemophilia B show a strong preference for residues that are conserved in the homologs of FIX: FVII, FX, and protein C. Thus, 291 different substitutions have been found at the 107 residues that are absolutely conserved, 113 at the 73 amino acids that show only one or two conservative changes, 58 at the 45 residues that show one nonconservative change, and 90 at the 229 less-conserved amino acids.

The current list of hemophilia B mutations also identifies residues that are mandatory for the structural and/or functional integrity of FIX because different types of substitutions are associated with hemophilia B. Thus, 53 residues show two different substitutions, 48 show three, 32 show four, 8 show five, and 5 show six. The last two groups comprise Glu_{33}, Pro_{55}, Cys_{88}, Cys_{95}, Cys_{132}, Arg_{145}, Arg_{180}, Cys_{222}, Cys_{361}, Asp_{364}, Ser_{365}, Thr_{380}, and Ser_{384}. The abundance of FIX residues that are known to have suffered multiple substitutions also suggests that the data available on hemophilia B mutations already form a fairly good representation of the mutational spectrum of hemophilia B. We have also calculated the target for single base substitutions causing hemophilia B. This comprises 825 substitutions of which 189 are expected to cause nonsense and 636 missense mutations. The current list of observed hemophilia B mutations in fact contains 73 different nonsense and 554 different missense mutations that represent 38.6% and 87%, respectively, of the total number expected.

3.3 Functional Interpretation of Observed Sequence Changes and Correlations between Genotype and Phenotype

The criteria that can be used to decide whether an *F9* sequence change observed in a hemophilia B patient is the cause of the disease are essentially those already mentioned for mutations of the *F8* gene and hemophilia A. The lack of a convenient source of FIX mRNA of course prevents the analysis of most mRNA processing defects and the clear identification of intronic mutations capable of causing hemophilia. Fortunately, the systematic analysis of hemophilia B populations indicates that no more than 1–2% of the *F9* mutations are likely to be in regions other than the proximal promoter, exons, and normal RNA processing signals. Thus, the lack of mRNA precludes the rapid detection of only a very small proportion of the hemophilia B mutations.

As in hemophilia A, gross deletions, frameshifts, and nonsense mutations are usually associated with a severe phenotype and predisposition to the inhibitor complication. The latter was recognized as early as 1983 in hemophilia B. Patients with hemophilia B bearing identical mutations appear to show less phenotypic variation than analogous groups of patients with hemophilia A. Comparison of FIX coagulant activity and protein concentration in blood may indicate whether mutations

merely affect the function or also the secretion and/or stability of Factor IX. Thus, the prepeptide mutation I-30N, which alters one of the essential features of the prepeptide (its hydrophobic core) and may thus affect secretion, and also substitutions at cysteines involved in disulfide bridges, which may affect stability, are associated with low protein levels. Conversely, mutations affecting key functional residues such as Asp_{369} and Ser_{365} show normal protein levels.

4 Considerations Arising from the Study of Mutations in Hemophilia A and B

It is instructive to compare some features of the molecular genetics of hemophilia A and B. These two diseases are clinically indistinguishable and their differential diagnosis requires specific coagulant assays. Nevertheless, once hemophilic patients are separated into the A and B groups, some differences emerge. In hemophilia A, a much larger proportion of patients is severely affected. This is explained by the *F8* gene proclivity to disruptive inversions involving the *int1h* and *int22h* sequences. This difference in the hemophilias' mutational spectra (see Figs. 4 and 8) also largely explains why 20% of hemophilia A and only 3% of hemophilia B patients develop inhibitors during the course of replacement therapy.

The amino acid sequence of FIX appears much more constrained than that of FVIII because while 4.2% of all *F8* missense mutations are thought to be able to cause hemophilia A, that is so for 21.2% of the *F9* missense mutations. Since the B domain of FVIII represents 39.3% of the FVIII polypeptide and does not participate in coagulation, the above difference is largely but by no means entirely due to this domain. Thus, the apparent correspondence between the ratio of the sizes of *F8* and *F9* and the ratio of the incidence of hemophilia A and B appears to result from three main factors: the predisposition of the *F8* gene to disruption by inversion, the presence in FVIII of the large B domain that tolerates amino acid substitutions, and the more constrained structure of FIX.

The study of an unbiased sample of hemophilia B patients representing 72% of the UK population has allowed a direct estimate of the hemophilia B mutation rate and of the rates of different types of mutations. Thus, transitions at CpG sites appear to occur at the rate of 97×10^{-9} per nucleotide per generation, transitions at other sites at the rate of 7.3×10^{-9}, transversion at CpG sites at 5.4×10^{-9}, and transversions at other sites at 7.0×10^{-9}. Hence, the rate of transitions at CpG sites is 13-fold greater than other base substitutions. While this explains the deficit of CpG doublets observed in the human genome, it is still insufficient to explain the proportion of hemophilia B (34.8%) or hemophilia A (32.3%) mutations due to transitions at CpG sites. A full explanation must consider natural selection at essential sites of the coding regions of *F8* and *F9*. At these sites, selection will oppose the tendency to lose CpG doublets. Consequently, CpG sites are relatively more frequent at critical sites of gene coding regions, and their mutations are, therefore, particularly likely to cause disease. In keeping with this idea, we observe that of the 96 base substitutions that can occur at CpG sites in the coding sequence of the *F9* gene, 58, or 60%, are expected to cause hemophilia B, while only 767, or 24% of the 3179 base

substitutions at other sites are expected to cause the disease.

5 Mutational Heterogeneity and Genetic Counseling in the Hemophilias

The great mutational heterogeneity of hemophilia A and B is a problem with regard to the carrier and prenatal diagnoses that are required for precise genetic counseling.

In the hemophilias, coagulant assays often do not provide definite carrier diagnoses because the vagaries of X chromosome inactivation result in broad variation of FVIII or FIX values in carriers and considerable overlap between carrier and normal females.

The analysis of the intrafamilial segregation of intragenic polymorphic markers may provide definite carrier diagnoses as well as first trimester prenatal diagnoses but it inevitably fails in a large proportion of cases. The diagnostic failures are due to the limited informativity of available polymorphic markers in the population of interest, to the logistic problem of obtaining samples from all required individuals, and especially to the large proportion of families that have a single affected individual. For example, in the United Kingdom and Sweden, approximately 50% of the families with hemophilia A or B have a single affected individual and the polymorphic marker approach is of very modest value in these families.

Only the direct detection of the gene defect can offer maximum diagnostic success. Therefore, we have argued that ideal strategies to optimize genetic counseling in the field of hemophilia should be based on the construction of national confidential databases of mutation and pedigree information. This can be achieved by characterizing the mutation of an index individual in each family and collecting his/her pedigree. Such national databases are now being constructed in the United Kingdom and other developed countries. They, of course, provide information on the molecular biology of the disease and allow very rapid carrier and prenatal diagnoses on the blood relatives of the index individuals because such diagnoses can be based simply on the analysis of the region of the gene that is defective in the index person.

A further concern in genetic counseling is the issue of somatic or gonadal mosaicism for the hemophilia A or B mutations. Since mutations in the *F8* or *F9* gene may arise postzygotically, individuals who have suffered such a mutational event may have a mixture of cells that either have or have not a hemophilia mutation. If this mixture is present in somatic tissues, the individual is a somatic mosaic, while if the mixture is confined to germline tissue he/she is a gonadal mosaic. Anecdotal evidence for somatic mosaicism is available for both hemophilia A and B, and evidence for gonadal mosaicism has been presented for Duchenne muscular dystrophy. In general, mosaic status will be found in an individual who is the first in the family to carry the relevant mutation, but exceptionally a mosaic may result from a zygote with two or more X chromosomes such that the X chromosome carrying a preexisting hemophilia mutation is lost from some of the cells during postzygotic development.

Obviously, it is impossible to predict the risk of a mosaic mother transmitting the mutant gene to her offspring as this will depend on the proportion of eggs carrying the mutant gene and their chance of maturation. Genetic counseling

will therefore generally have to rely on estimation of average empiric risks. This can be obtained from careful, unbiased population studies. Thus, in the UK population, we investigated how many hemophilia B patients or carriers could be attributed to gonadal mosaicism in mothers designated as noncarriers when their leucocyte DNA was tested. Since we observed no patients or carriers from 47 informative births in the UK hemophilia B population, we concluded that the empiric risk of a ''noncarrier'' mother of a hemophilia B patient manifesting as a gonadal mosaic by transmitting the mutation to a second child was less than 0.062.

In the case of detectable somatic mosaicism, the upper limit of risk given should be that appropriate to carrier mothers, and, if requested, prenatal diagnosis should be undertaken.

Of course, the chance of detecting somatic mosaics depends on how efficient the laboratory test is in identifying the mutant DNA mixed with that of wild type. For this purpose, mutation detection methods based on chemical mismatch cleavage or denaturing gradient high-performance liquid chromatography are preferable to sequencing.

6 Progress in the Treatment of Hemophilia

In the second half of the last century, therapies based on concentrates of FVIII and FIX prepared from human plasma increased the patients' life expectancy to near-normal values. However, in the 1980s, HIV-infected blood products created a cohort of patients suffering from this lethal disease. Similarly, high rates of hepatitis C infection have marred the progress achieved with the introduction of blood-derived coagulant concentrates. Moreover, recently, concern has arisen about the transmission through blood products of the Creutzfeldt–Jakob prion disease.

Fortunately, the early cloning of the *F9* and *F8* genes has allowed the development of industrial procedures for the production of both FIX and FVIII from mammalian cell cultures created to express these factors *in vitro* so as to minimize risks from the above-mentioned viruses and prions.

In the last 18–20 years, gene therapy has been an important treatment aim. The hemophilias appear well suited to this type of approach because there is no need to ensure tight regulation of the expression of the corrective gene, and any site of expression allowing the coagulant factor to reach the blood circulation should be suitable. Moreover, the enhancement of coagulant level required for the success of this approach is relatively modest because even an increase of 1–2% of the normal level can produce important clinical effects such as transforming severe disease into moderate disease and reducing the number of spontaneous bleeding episodes experienced by the patient. A substantial body of work has been done to develop suitable expression constructs, using retroviral vectors or vectors derived from DNA viruses such as adenovirus or adenovirus-associated virus, and systems of delivery for both *in vivo* or *ex vivo* approaches to treatment (i.e. the injection of expression constructs *in vivo* or the modification with the expression constructs of the patient's cells *ex vivo* followed by culture and expansion *in vitro* and then reinjection into the patient).

Model animals were then used to test various therapy schemes and some

experiments were positive enough to allow initiation of clinical trials, mainly in the United States. Thus, 13 hemophilia A patients, known to have HIV and hepatitis C, and expected to be at very low risk of developing inhibitors, were infused with amphotrophic retroviral vectors for FVIII expression at doses between 3×10^7 and 9×10^8 viral particles (vp) per kilogram; no significant benefit ensued.

Eight hemophilia B patients were injected intramuscularly with an associated adenovirus vector of serological type 2 (AAV2) for FIX expression and one patient receiving the lowest dose was reported to show 1–2% FIX levels for 40 months, but at higher viral doses, no significant FIX level was observed and in all patients the development of antiviral antibodies precluded readministration of the vector.

Administration of factor IX constructs in AAV2 vectors via the hepatic artery in two patients at a dose of 10^{12} vp/kg resulted in transient FIX levels of 10–12%.

In a further trial, autologous skin fibroblasts from six patients were transformed by electroporation with an FVIII expressing plasmid and expanded *in vitro* so as to inject $1–4 \times 10^8$ cells in the patients' greater omentum. Four patients showed FVIII levels above pretreatment values but these returned to baseline values in all patients after 12 months.

Thus, clinical trials have not yet led to satisfactory treatment schedules but since they have not revealed significant toxicity in the patients treated so far, they leave the door open for future advances. These, of course, will always have to consider patients' safety as paramount because established replacement therapy is reasonably effective in both hemophilias and any new treatment must achieve better results with no increase in risk.

Keywords

DNA Modification
Enzymatic addition of chemical groups to DNA occurring after DNA synthesis; in eukaryotes, most commonly methylation of cytosine.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Volume 6

Epigenetics
A mode of gene regulation, based not on the DNA sequence itself but on stable packaging, heritable during cell division.

Heterochromatin
The silenced domains of chromatin, characterized as maintaining a condensed form, defined by a set of distinctive biochemical properties and cytological behaviors.

Heterochromatin Protein 1 (HP1)
A conserved protein predominantly associated with pericentric heterochromatin, capable of interacting both with a specifically modified histone and with the enzyme that generates the modification.

Histones
A family of low molecular weight proteins, very basic and evolutionarily conserved, which form the core structure for nucleosome assembly in chromatin formation.

Nucleosomes
The basic repeating subunit of chromatin consisting of a tetramer of histones H3 and H4 plus two dimers of histones H2A and H2B, with ca. 170 bp of DNA wrapped around in two left-handed turns; each particle connects to the next by a short stretch of linker DNA, which interacts with histone H1.

Posttranslational Modification of Proteins
An enzymatic addition or removal of various chemical groups to proteins (including histones) after synthesis, including acetylation, methylation, phosphorylation, and so on.

Repetitive DNA
The DNA sequences that are represented by multiple copies in the genome; the copies may be in tandem arrays or scattered as individual copies.

Transposable Elements
Various families of moderately repetitive DNA sequences originally capable of transposition; their distribution and numbers vary between different individuals and strains.

The genomes of eukaryotes are packaged in chromatin, a complex of DNA with histones in a nucleosomal array, and folded further through interactions with other proteins into higher order domains. The different levels of packaging help define whether genes are available for expression, as in euchromatin, or generally silenced, as in heterochromatin. The condensed heterochromatin domains are characterized

by a group of features, including low gene density, high levels of repetitious sequences, location at the nuclear periphery, late replication, and little recombination during meiosis, apparently reflecting a particular pattern of posttranslational modifications of the histones, association of heterochromatin-specific proteins, and regular spacing of nucleosomes.

1 Introduction

In 1928, Heitz observed that the staining of liverwort *Pellia epiphylla* interphase nuclei is not uniform, suggesting the presence of two fractions of chromatin as manifested by weakly stained areas and areas that maintain the intense staining of metaphase chromosomes. Weakly stained areas were designated as *euchromatin*, while the dark positively heteropycnotic areas were labeled *heterochromatin*. The fate of these regions was traced from interphase to metaphase and back to interphase; it was observed that these regions remained differentially stained in almost all phases of the cell cycle, showing a common level of condensation only in metaphase. The most prominent heterochromatic regions are located mainly in or close to the centromeres and telomeres of chromosomes. The development of better microscopes and application of various genetic, biochemical, and molecular approaches, coupled with the examination of different species in similar studies, have provided a much deeper understanding of the underlying mechanisms generating this different packaging. Table 1 describes the major differences between these two chromatin fractions, giving both cytological and biochemical characteristics. The reader should bear in mind that the differences described reflect the sum of many observations made in a wide range of different organisms, cell types, and so on. Heterochromatic regions may manifest all or only some of these features. It seems likely that a similar condensed chromatin organization can be achieved in different ways, using redundant molecular mechanisms. Recent data also indicate that some of the features characteristic of heterochromatin may be utilized to downregulate the expression of genes in euchromatic domains. This implies the existence in the nucleus of a continuum of chromatin states, potentially generated by various combinations of the features listed in Table 1.

Some of the properties of heterochromatin are reversible; several must be transiently altered or re-created following replication, indicating the presence of various mechanisms to accomplish this with fidelity. This, in turn, implies that the formation of heterochromatin (or heterochromatin-like structures) may be used as a mechanism of epigenetic inheritance, maintaining particular states (silent or activatable) of gene expression. The heterochromatin located around centromeres, telomeres, and some other regions maintained in that form in all cell types is usually referred as *constitutive heterochromatin*. Regions that show a cell-type-specific (or otherwise selected) heritable silencing of particular genes, chromosome domains or whole chromosomes are referred to as *facultative heterochromatin*. Many questions remain as to how constitutive and

Tab. 1 Distinctions between euchromatic and constitutive heterochromatic regions of complex genomes.

Feature	*Euchromatin*	*Heterochromatin*
Proportion of genome	50–80%	20–50%
Interphase appearance	Decondensed (lightly stained)	Condensed (densely stained – heteropycnotic)
Chromosomal location	Distal arms	Usually pericentromeric, telomeric
Nuclear location	General	Often clumped (nuclear periphery, around nucleolus)
Sequence complexity	High; unique DNA, interspersed middle repetitious sequences	Low; repetitious DNA: satellite DNA, blocks of middle repetitious sequences
Gene density	High	Low
DNA methylation	CpG islands hypomethylated	Fully methylated (in mammals and plants)
Histone modification;	High histone acetylation; specific amino acids are methylated	Low histone acetylation; specific amino acids are methylated
Nucleosome spacing	Irregular	Regular
Nuclease accessibility	Variable	Low
Mechanism of gene silencing	Individual genes	Large domains
Meiotic recombination	Normal	Absent or significantly decreased
Replication timing	Throughout S phase	Late S phase

facultative domains are targeted for packaging in a heterochromatic form, a process sometimes referred to as *heterochromatinization*. This article will summarize our current knowledge concerning the differentiation of chromatin into these two fractions, and the possible role of heterochromatin in genome organization and regulation of gene expression.

2 Cytological Observations

Observations using light microscopy showed that the dark heteropycnotic chromatin visible in interphase nuclei corresponds to the strongly stained domains in metaphase chromosomes surrounding centromeres and telomeres. Small, intensely stained islands within the chromosome arms, referred to as *interstitial* or *intercalary heterochromatin*, have been observed in chromosomes of some organisms. In interphase, the strongly stained domains lie at the periphery of the nucleus, close to the nuclear membrane. These observations were confirmed subsequently by immunostaining with antibodies to proteins specifically enriched in heterochromatin (see Sects. 3.3 and 3.4), and by *in situ* hybridization with DNA probes complementary to the repetitive DNA fractions that are concentrated around centromeres. Analyses using electron microscopy (EM) to examine interphase nuclei have also demonstrated the presence of two chromatin fractions, with the electronically dense, tightly packaged fraction located mainly at the nuclear periphery and around the nucleolus.

The patterns seen on EM photographs, by light microscopy after staining with dyes or immunostaining, or with *in situ*

hybridization of repetitious sequences, all indicate that heterochromatin in the interphase nucleus is organized in several large blocks, which tend to localize at the nuclear membrane. This suggests that the heterochromatic regions of different chromosomes in the interphase nucleus interact with each other, as the number of spots observed is smaller than the total number of centromeres and other heterochromatic regions. Careful analysis of the spatial organization of chromosomes within the nucleus of some organisms has shown that the distribution of heterochromatin is not random. The centromeres and surrounding pericentromeric heterochromatin tend to concentrate on one side of the nucleus, while telomeric regions of the same chromosomes are clustered on the opposite side. This phenomenon is often referred to as *Rabl orientation*, honoring Carl Rabl, who described it first in 1885. The positioning of the heterochromatic telomeres and centromeres implies that the euchromatic regions in between also assume defined positions within the nuclei. Direct observations have confirmed the existence of the so-called chromosomal territories with limited fixed positions for different chromosomal segments in specific areas of the nucleus.

While constitutive heterochromatin (e.g. pericentromeric and telomeric regions) is present in an invariant pattern at given sites and in given chromosomes, facultative heterochromatin is represented by chromosomal regions or whole chromosomes that are capable of existing in one state in some cells and in the other state in other cells. In some organisms, such as the mealy bug *Planococcus citri*, the full haploid set of paternal chromosomes is found in the heterochromatic state. Mammals demonstrate the well-known example of X-chromosome inactivation in female nuclei. The inactivated X-chromosome forms the so-called Barr body, usually identified as a condensed mass at the periphery of female nuclei. The number of Barr bodies correlates well with the number of inactivated X-chromosomes in cases in which the individual carries more than two X-chromosomes. Identification of the inactive X-chromosome as the condensed Barr body led to the suggestion that the formation of heterochromatin might be a mechanism for downregulating gene expression. In the normal situation, this inactivation serves to compensate for the differences in dosage of X-chromosomal genes between females, with two X-chromosomes, and males, with single X-chromosome. X-chromosome inactivation serves to diminish the negative effect of additional X-chromosomes, and such aneuploids survive, while most cases of human aneuploidy (extra copies of a chromosome) are lethal. While the decision of which X chromosome to inactivate appears to be random in somatic cells, the decision once made is stably inherited through multiple rounds of mitosis, a critical observation indicating that changes in chromatin structure play a role in epigenetic inheritance. In these cases, gene activity is determined not by the DNA sequence *per se*, but by the particular packaging of the gene in chromatin.

A second phenomenon demonstrating the link between gene inactivation and the location and packaging of a gene in a heterochromatic form is position effect variegation (PEV), described in Drosophila, yeast, and mammals. In these cases, a gene normally located in a euchromatic environment is positioned adjacent to or within heterochromatin by chromosomal rearrangement or transposition (Fig. 1).

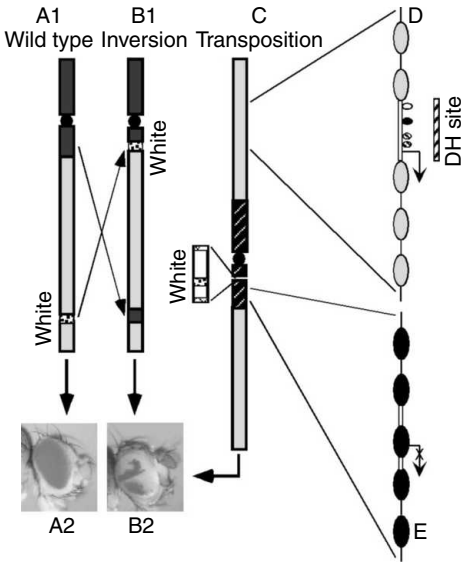

Fig. 1 Position effect variegation in Drosophila. (A1, A2) The wild type *white* gene (spotted rectangle) is required to generate red fly eyes; it is localized in a euchromatic segment (light grey) of the X chromosome. (B1, B2) Inversions of the chromosome segment with one breakpoint in pericentromeric heterochromatin (black) and one breakpoint adjacent to *white* position the gene adjacent to heterochromatin, leading to inactivation of the gene in some eye progenitor cells, resulting in a variegating phenotype. (C, B2) The same result is observed when *white* is transposed into heterochromatin as a part of a transposon. (D) Genes in euchromatic domains are generally packaged in an irregular pattern of nucleosomes (grey ovals); one observes accessible (open, nucleosome free) sites at or near the 5′ end of genes, allowing interaction with transcription factors (small circles) that can regulate initiation of transcription from the start site (bent arrow). Such open sites are often called DH sites (DNase I hypersensitive sites) or HS sites (hypersensitive sites) because they are readily cleaved by nucleases. (E) In heterochromatic domains, the nucleosomes (black ovals) have a characteristic, different pattern of histone modification, and interact with a subset of chromosomal proteins, some specific to these domains. Within heterochromatic regions, the nucleosomes show very regular spacing, and appear to mask promoters and other regulatory sites, inhibiting transcription (crossed bent arrow).

In both cases, one observes that the gene is stochastically inactivated in some cells, but remains active in others, resulting in a variegating phenotype; the active or inactive status, once set, is mitotically inherited in the progeny of the cells, while the phenotype, at least in yeast, is stably maintained over many generations, that is, through meiotic divisions. The variegating gene in such situations is now found located close to the nuclear periphery, with heterochromatin, at a higher frequency. Inactivation of some genes during normal development may occur concomitantly with their spatial relocation to heterochromatin domains. Genetic analysis has shown that a screen can identify mutations in other loci that suppress or enhance the pattern

of variegation, observed as a loss in the reporter gene silencing or an increase in reporter gene silencing. Such second-site modifiers have frequently been found to be genes that encode chromosomal proteins, or proteins required for chromatin assembly and function. The study of such suppressors and enhancers of variegation [*Su(var)*s and *E(var)*s] has greatly facilitated studies of the biochemical properties of heterochromatin and the resultant epigenetic marks.

3 Biochemical Characteristics of Heterochromatin

3.1 DNA in Heterochromatin

Kinetic analysis of the renaturation of genomic DNA has shown that the genomes of higher eukaryotes are made up not only of unique sequences (present in one copy per haploid genome), which renature slowly, but also of repetitious sequences (present in multiple copies per haploid genome), which renature more quickly. Constitutive heterochromatin is enriched in repetitive DNA and has relatively little unique DNA. Most of the genes encoding proteins are present in a single copy. Genetic analysis has identified only a few loci that map within the pericentric heterochromatin. Sequencing of several eukaryotic genomes has confirmed the conclusion that heterochromatin is gene-poor, and provided more precise knowledge about the distribution and features of DNA in both chromatin fractions. Interestingly, analysis of the DNA sequences from Drosophila has predicted the presence of at least ~100 genes embedded in the pericentric heterochromatin; thus, while it is gene-poor, the region is not devoid of genes.

Repetitive DNA may be roughly divided into two classes based on the copy number – middle repetitive and highly repetitive DNA. Genes encoding the large ribosomal RNAs, 5S RNA, and histones fall into the middle repetitive class in most eukaryotic organisms. However, the majority of the middle repetitive DNA consists of intact and/or damaged transposable elements. In some organisms, including humans, up to ca. 50% of the DNA is derived from transposable elements, representing different families, including pro-retroviruses. These repeats can be scattered as single copies, found at apparently random sites within genomic DNA, or may be grouped in tandem or inverse arrays. Sometimes different transposable elements are found nested together, one inside of another. Just as unique DNA sequences are characteristic of euchromatin, a high frequency of clusters and/or nested copies of moderate repeats/transposable elements is also a feature of heterochromatin. A significant fraction of the transposable elements, particularly those copies in heterochromatin, carry various mutations that render them incapable of transposing.

Several investigations have suggested that the presence of repetitious elements may serve as a signal for targeting formation of heterochromatin. For example, the *Drosophila melanogaster* gene *white* is normally found at a euchromatic site and is fully expressed, giving flies a red eye; however, a tandem array of *white* genes, generated from a transgene, results in inactivation, regardless of the site of insertion within the chromosomes, leading to a variegated eye phenotype. This variegation, similar to PEV, is the result of stochastic inactivation of the cluster

of *white* genes in some progenitor cells of the eye in which this gene is normally active. However, the presence of repetitive DNA is not sufficient to trigger the formation of heterochromatin in all cases. For example, the histone genes, repetitive in most eukaryotes, are not packaged in cytologically visible heterochromatin, nor do they manifest other biochemical characteristics of heterochromatin. However, the repetitious rRNA genes, found in the nucleolus, can manifest heterochromatic properties, including the silencing of marker genes inserted into this domain.

The second class of repeats, present almost exclusively in heterochromatin, is highly repetitive DNA, also known as *satellite* DNA. Satellite DNA consists of short sequences (from ca. 10 bp to a few hundred bp) repeated in tandem arrays up to a million times. Some satellite DNA fractions are chromosome-specific, while others occur on all chromosomes, though in varying amounts. In some species, including the kangaroo rat *Dipodomys ordii* and some beetles from the coleopteran family *Tenebrionidae*, satellite DNA accounts for the majority of the genomic DNA. If the base composition of a given repeat is GC- or AT-rich, that DNA may be separated from the bulk of the DNA in a cesium chloride (CsCl) density gradient, giving a separate ''satellite'' peak, heavier or lighter than the bulk DNA, respectively. Single copies or clusters of transposable elements often interrupt such arrays. Cloning and sequencing of the DNA in the boundary regions between heterochromatin and euchromatin (often called transition zones) has shown that this part of the genome consists of a considerable mix of both types of repeats, with an intermediate density of genes.

The pericentromeric location of the most highly repeated sequences raises the question of their possible participation in the formation of the centromere (the constriction that serves as a platform for assembly of kinetochore proteins) and the kinetochore (the complex of proteins to which the nuclear spindle fibers (microtubules) attach to accomplish chromosome segregation). The matter is controversial, with several competing points of view. Some evidence has suggested that satellite DNA is both necessary and sufficient to form a centromere, while other experiments indicate that there is no requirement for a particular DNA sequence. In the latter view, the centromere is a specialized chromatin structure maintained in an epigenetic pattern. This structure may arise in different ways, for example, with the help of specific proteins such as the centromere-specific histone CENP-A, a histone H3 variant.

In addition to pericentromeric heterochromatin, differentially stained regions that have many characteristics of heterochromatin are found near or at telomeres. In most organisms, the telomere consists of $(TG)_n$ repeats that interact with a group of specialized proteins, creating a specific chromatin structure. The system enables telomeres to support DNA replication without any loss of DNA due to unidirectional copying, to prevent the fusion of chromosome ends, and to direct the chromosome ends to sites close to the nuclear membrane. Localization is thought to involve interactions between telomere proteins and the nuclear lamina, a structure just below the inner nuclear membrane. Drosophila differs in having clusters of particular transposable elements at the ends of the chromosomes, flanked downstream by different satellite-like repeats – telomere-associated sequence (TAS). It is unclear

which feature – DNA sequence and/or proteins – makes telomeric regions in all organisms heterochromatic. Studies of genes affecting PEV of visible markers transposed into or close to telomeres have shown that while many of the same genes affect silencing in telomeres and mating-type loci in *Saccharomyces cerevisiae*, different groups of genes influence telomeric and pericentric PEV in Drosophila. This implies a different chromatin structure in telomeric and pericentromeric heterochromatin in this organism.

3.2 Modification of DNA in Heterochromatin

In mammals and plants (but not in Drosophila or yeast), there is a strong correlation between heterochromatic regions of chromosomes and the degree of DNA methylation. Historically, the role of DNA methylation in gene silencing and formation of heterochromatin was first demonstrated by the observation that DNA of the inactive X-chromosome is hypermethylated. Methylation in mammals usually occurs behind the replication fork at position C5 of cytosine bases in CpG dinucleotides. C-residues in other sequences have been found to be modified, but at a lower frequency. This modification does not occur exclusively within heterochromatic domains. Many euchromatic genes have CpG-rich elements (so-called ''CpG islands'') in their 5′ upstream region, which are important for the regulation of the gene through interaction with the transcriptional regulatory protein Sp1. Methylation of these islands is usually an indicator of gene silencing; presumably, methylation blocks binding by Sp1 to its target sequence. Removal of 5′mC (for example by replicating DNA in the presence of 5-azacytidine, a form of C that cannot be methylated) can reactivate these genes. The same drug can activate silenced genes on the inactive X-chromosome in female mammalian nuclei.

DNA methylation is a reversible process. Only the parental strand of any newly replicated DNA double helix will contain the methylated cytosine. In the usual situation, this remaining 5′mC will interact with 5′mC-binding proteins that direct site-specific enzymes, the maintenance DNA methyltransferases, to methylate the cytosine of the CpG on the opposite DNA strand. If this interaction is blocked, or if this interaction and subsequent modification fails for any reason, the DNA of half of the granddaughter cells will lose 5′mC at this site. However, a second group of DNA methyltransferases has been identified that are capable of *de novo* methylation of cytosines on the nonmodified DNA template. These DNA methylases restore methylation of some genes and in heterochromatin after the massive demethylation of DNA that occurs as part of normal early development in mammals. We do not know, however, how these enzymes are targeted to the sequences that need to be so modified. Some sequences that one might expect to be silenced are not demethylated during this general event, among them proviral sequences of IAP particles (which resemble transposable elements in the mouse genome) and imprinted genes. Imprinted genes are expressed specifically from the chromosome inherited from the mother or the chromosome inherited from the father, with the allele from the other parent being silenced. Not surprisingly, these genes in mammals exhibit differential DNA methylation; the silenced genes show additional features of facultative heterochromatin.

3.3
Histone Modifications and Chromatin Structure

The different cytological appearance of heterochromatin has led to the suggestion that the molecular organization and DNA packaging in the underlying chromatin must be different. Data from the last few years has shed significant light on this subject. Chromatin is a chain of repeating subunits (nucleosomes) of ca. 200 bp, with approximately 146 bp of DNA folded around a histone octamer (core) consisting of a tetramer of $(H3 + H4)_2$ and two dimers of (H2A + H2B). These core particles are joined together by short (20–60 bp) linkers, which are generally associated with histone H1, other linker histones such as H5, or HMG proteins. Nucleosome location can generally be regarded as sequence-independent, although DNA characteristics such as bendability can influence nucleosome positioning. Histones interact with each other to form the octamer and bind DNA primarily through their histone-fold domains, leaving their N-terminal tails available for other interactions. Presumably these interactions stabilize the higher-order folding of the basic chain into 30 nm fibers and higher order packaging arrays. Posttranslational modification of the histones plays a major role in determining their interactions with other chromatin components (DNA, other histones, and non-histone proteins), and hence in stabilizing or destabilizing higher order structures.

The most common *in vivo* modifications are acetylation, methylation, phosphorylation, ubiquitination, or polyADP-ribosylation. Most of the sites of modification are clustered in the N-terminal regions, changing the total charge and hydrophobicity of a given histone tail. In addition, several sites of modifications have been described in the central histone-fold motifs. Histone modifications are catalyzed by enzymes that introduce or remove certain groups at one or more positions. The enzymes are often present as part of large multimeric chromatin-remodeling complexes, targeted by associated gene-specific activators and repressors. The very complex pattern of histone modifications has led to the idea of a histone "code," defining different packaging states. In particular, modification of histone H3 by methylation at lysine 9 (giving H3-mK9) has been associated with packaging into heterochromatin, while acetylation in general, and acetylation of H4 at lysine 5 and lysine 8 specifically, are associated with packaging in euchromatic form.

A second type of complex, the ATP-dependent chromatin remodeling complex, defines nucleosome formation behind the replication fork and/or destabilizes nucleosomes in an already mature nucleosomal array. All remodeling complexes of this type include a subunit possessing a DNA- and/or nucleosome-inducible ATPase activity. Various versions of these complexes are simultaneously present in a given cell, modified by the temporary addition or removal of different subunits. Such complexes are involved in both activation and repression of many genes. The exact composition of the complexes, their targets for action, and their mechanism(s) for localization at the appropriate targets are all currently under investigation. Complexes of both types, capable of histone modification and of ATP-dependent remodeling, are essential for gene activation, as even within euchromatic domains nucleosome arrays render many enhancer

and promoter sites inaccessible to regulatory proteins and/or general transcription factors and RNA polymerase. In addition, nucleosomes suppress RNA elongation during transcription.

Nucleosome arrays in heterochromatin are structurally similar but not identical to those in euchromatin. Digestion of chromatin with micrococcal nuclease reveals a more regular spacing in heterochromatic arrays, with a narrower cleavage site in the linker. Heterochromatic regions, overall, are less accessible to both general and site-specific nucleases, and to most other reagents that interact with DNA. These properties suggest that some characteristic features of nucleosome structure, positioning, and mobility are different in heterochromatin and euchromatin, presumably reflecting differences in internucleosomal interactions as well as differences in the associated chromosomal proteins. These changes may be due to the various histone modifications mentioned above. Certainly the average pattern of histone modifications differs between heterochromatin and euchromatin, creating a distinct signature for each domain using the histone code. However, the histone modification pattern is likely to vary for different genes in a given domain (e.g. for euchromatic genes that are actively being transcribed vs. not being transcribed; for inducible vs. uninducible genes, etc.), and for different types of heterochromatin, creating a continuum of chromatin states. The discovery of the patterns of posttranslational histone modifications, with the realization that enzymes responsible for the modifications had in some cases been previously identified as activators or repressors of gene expression, was one of major recent breakthroughs in the chromatin field.

The differences in heterochromatic nucleosome arrays, specifically the more regular spacing, have suggested that specific chromatin-remodeling complexes might be involved in assembling heterochromatin. *In vitro* assays have demonstrated that two Drosophila chromatin remodeling complexes, CHRAC and ACF, can generate arrays with heterochromatin-like regular spacing. The human WSTF–ISWI and ACF complexes appear to be the mammalian homologs of CHRAC and ACF, based both on their composition and by their ability to space nucleosomes regularly on DNA. These complexes are concentrated in heterochromatic regions in late S-period, the time when the bulk of the heterochromatin is replicated.

3.4 Specific Heterochromatin Proteins

Heterochromatin is concentrated in the pericentric and telomeric regions, and is rich in satellite DNA and other repetitious DNA. Several different proteins that specifically interact with satellite DNA have been found in vertebrates and in Drosophila. Most of these proteins interact as well with homologous sequences scattered in euchromatic regions, and some also function in the regulation or chromatin organization of euchromatic genes. Most of these proteins interact with other proteins to form multimeric complexes. For example, Drosophila GAGA factor, the protein specifically interacting with $(GA)_n/(CT)_n$ short repeats in the promoter regions of many genes, regulating their expression, is found also to interact with $(AAGAG)_n$ and $(AAGAGAG)_n$ satellite DNA fractions, concentrated in the pericentromeric heterochromatin of several chromosomes. This protein has been found in several multimeric complexes, and interacts

with the chromatin-remodeling complex NURF. Interestingly, mutations in GAGA factor enhance PEV of genes transferred to heterochromatin, suggesting that its dominant role is in support of gene expression. Whether GAGA factor association has an impact on the chromatin structure of the satellites where it binds is yet to be demonstrated.

The first protein specifically characterized as a heterochromatin protein, Drosophila Heterochromatin Protein 1 (HP1), binds poorly to DNA, with little specificity. HP1 is thought to play a structural role in heterochromatin, since an antipodal dosage dependence is observed: PEV is suppressed by mutations in the gene for HP1 that result in a loss of functional HP1, and is enhanced by an increase in the amount of HP1, for example from a duplication or a transgene. This type of action is also observed for a few other chromosomal proteins, *SU(VAR)3–9* (an H3 methyl-transferase), *SU(VAR)3–7* (a zinc finger protein), and HP2 (a potential structural protein). Homologs of HP1 have been found in the yeast *Schizosaccharomyces pombe*, worms, other insects, amphibians, mammals, and plants. Full inactivation of HP1 through loss or missense mutations, or by the expression of intracellular antibodies, is lethal. From one to three HP1 homologs have been identified in different organisms, but the proteins are not identical, nor can they substitute for each other in a genetic analysis; all are required. Immunocytological analyses indicate that the homologs have different patterns of nuclear distribution, with only one of them restricted to pericentric heterochromatin. The three proteins in mammals can physically interact with each other. In transgenic Drosophila, expression of the genes for the HP1 human homologs also enhances PEV, suggesting a conserved functional interaction with the Drosophila machinery that establishes and maintains heterochromatin, including the originally identified HP1, encoded by *Su(var)205*.

The HP1's are small proteins, ca. 200 to 250 amino acids, with two conserved domains joined by a more variable hinge region. The N-terminal chromo domain was first recognized by homology with a conserved domain of Polycomb, a protein required for developmentally maintained silencing of homeotic genes in the euchromatin. The chromo domain has since been identified in several other chromosomal proteins. HP1 can dimerize through interactions involving the chromo shadow domain, and this structure appears to form a platform for interactions with many other chromosomal proteins, including *SU(VAR)3–9* and HP2.

The binding of HP1 to nucleosomes is facilitated by methylation of lysine 9 in histone H3, a histone modification characteristically enriched in heterochromatin. The modified histone tail fits nicely within the fold generated by the HP1 chromo domain. Missense mutations that lead to a loss of *Su(var)* activity (loss of silencing) are mutations that result in a loss of this stable interaction. This H3 modification is driven by one (or perhaps more) specific histone methyltransferase encoded by homologous genes found in mammals, yeast (*S. pombe*) and Drosophila. The founding member in Drosophila is *SU(VAR)3–9*. As the name implies, mutations of the gene encoding this protein suppress the PEV in Drosophila. This enzyme in mammals and flies forms complexes with HP1 and often colocalizes with HP1 in heterochromatic regions of chromosomes. The ability of HP1 to interact with both the modified histone (H3-mK9) and the enzyme responsible for the modification

suggests a mechanism for epigenetic inheritance of the modification pattern, and for the spreading of a heterochromatic domain once initiated.

HP1 can also interact with various proteins that are associated with repressor activity in euchromatic domains. The best-studied cases are in mammals. Gene repression is generally accompanied by histone deacetylation and, at least in some cases, by methylation of histone 3 at lysine 9. For example, a complex of mammalian HP1, SUV39H1, and the transcriptional repressor Rb has recently been described. Retinoblastoma protein (Rb) plays an important role in the induction of the G1-S transition during the cell cycle; mutations of Rb have been associated with several tumors. It has been suggested that Rb acts as a negative regulator by binding SUV39H1 (the human homolog of *SU(VAR)3–9*), resulting in local methylation of lysine 9 of histone H3, thereby recruiting HP1 to "fix" the gene in an inactive state. The process in this case is highly specific, involving only one nucleosome located on the promoter element of the cyclin D gene, repressed by Rb *in vivo*. Rb has also been found in complexes with histone deacetylase. It is unclear whether both silencing complexes are essential for complete inactivation, or whether cells and genes may choose between these modes of inactivation, one (deacetylation) being easily reversible, the other (methylation) being stable through generations. Since SUV39H1 cannot methylate acetylated lysine 9 in histone H3, the order of events seems obvious in this case. However, it is unclear whether the process can stop after the first step (deacetylation) without progressing to the next step (H3 methylation and binding of HP1). These data (and more) suggest that heterochromatin proteins play roles beyond the packaging of heterochromatic domains, being involved in regulating the activity of targeted euchromatic genes. It is unclear, however, how these processes are managed to limit the silenced domain to one or a few nucleosomes, whereas heterochromatic domains appear able to spread over large distances (at least 10 kb, observed in *S. pombe*).

4 Heterochromatin Behavior

4.1 Self-association

Many of the proteins enriched in heterochromatin, including HP1, are able to form homomeric and heteromeric complexes. This no doubt contributes to the association of heterochromatic regions in a small number of blocks, easily visible on a cytological level. This property of heterochromatic proteins may be utilized as a mechanism for gene inactivation. The best studied case involves the Ikaros family proteins, recently analyzed in mammalian pre-B cells. Several homologous proteins of this family have two domains, one participating in protein–protein interactions and the other in DNA binding. The Ikaros proteins show sequence-specific binding to DNA and form homo- and heteromeric complexes with each other. Most of the target sequences are multiple short repeats comprising a satellite DNA fraction concentrated in pericentric heterochromatin. However, identical short repeats are present in the regulatory regions of many genes. Ikaros suppresses the activity of the terminal deoxynucleotidyl transferase gene at the appropriate stage of lymphocyte differentiation by competing with a gene-specific activator for a partly overlapping binding site. Reduced chromatin accessibility for restriction enzymes and DNA

methylation are observed at the promoter of the repressed gene. Importantly, the inactivated gene is placed within or next to a heterochromatin block, most likely due to the formation of multimeric complexes between the Ikaros protein bound at the promoter and that bound in the pericentric heterochromatin. Whether or not silencing is dependent on this relocalization remains to be seen. Similar observations of relocalization have been made for some other genes in this cell lineage.

4.2 Late Replication

Early observations on incorporation of labeled precursors during DNA synthesis showed that the diffuse weakly staining euchromatin was replicated primarily during the first half of S-phase, while the heteropycnotic heterochromatic regions showed incorporation of label primarily during the second half of S-phase. These observations were confirmed by direct analysis of replication times for different DNA sequences: those enriched in constitutive heterochromatin were replicated at the end of S-phase. The same observations have held true for chromosomes and for separate chromosomal domains that showed the characteristics of facultative heterochromatin. For example, the inactive X-chromosome replicates late in S-phase, while the active X replicates early. It is still unclear what drives this replication schedule. There are many possibilities, ranging from the idea that the densely packaged heterochromatin may be less accessible to the replication machinery, to the suggestion that replication of heterochromatin requires proper amounts of specific chromatin-remodeling complexes such as WSTF–ISWI and ACF.

4.3 Recombination

Careful genetic mapping in several eukaryotes has shown that the frequency of recombination is usually significantly decreased toward centromeres and telomeres. Crossing-over is very low near heterochromatin domains in general. Similar observations have been made for regions located within or close to the silenced mating-type loci in yeast (*S. cerevisiae*), domains that appear heterochromatic by the criteria discussed above (silencing of transposed reporter genes, low accessibility to nuclease digestion, lack of histone acetylation, etc.). We do not know why heterochromatic regions are less susceptible to recombination. The ability of heterochromatic regions to ''stick together'' should facilitate the exchange of genetic material. In fact, spontaneous or induced chromosomal rearrangements with breakpoints in heterochromatin are seen more frequently then those with breakpoints in euchromatin. Of course, this may be explained simply as a consequence of the more frequent survival of the resulting progeny, due to the low gene density in regions of constitutive heterochromatin. A plausible explanation might lie in the inaccessibility of densely packed chromatin in this region to the recombinational machinery.

5 Conclusions: Euchromatin/Heterochromatin Relationships

The above discussion has provided many examples that point to the differences between heterochromatin and euchromatin, while at the same time emphasizing that no one single feature provides

a unique identifier of heterochromatin. A constellation of several characteristics is required to define a region as heterochromatic, and this combination may be different in different heterochromatic domains. For example, HP1 is commonly associated with pericentric heterochromatin, but is not associated with the inactive X-chromosome in mammals. Furthermore, different organisms may employ different strategies to generate a heterochromatic domain – one that has a regular chromatin structure, is inaccessible to a variety of probes, and is lacking in meiotic recombination. For example, while many plants and animals (notably mammals) utilize DNA methylation as a heritable mark of heterochromatin formation and gene silencing, Drosophila, yeast, and many other organisms do not appear to exhibit significant levels of DNA methylation. While organisms from the yeast *S. pombe* to Drosophila and humans utilize a strategy of H3-K9 methylation and HP1 association to form heterochromatin, the yeast *S. cerevisiae* does not. It is clear that higher eukaryotes have a number of histone methyltransferases that can modify H3-K9, and that these play both overlapping and distinct roles. Histone H3 and H4 hypoacetylation does seem to be a common strategy, but one used in different ways in different organisms. There has been some speculation that the range of biochemical mechanisms used by an organism to maintain heterochromatin structure, and concomitant silencing, may reflect the size of its genome. This may be correlated with the load of retroviruses and transposable elements – sequences that need to be silenced – commonly carried in the genomes of organisms with higher C values.

While heterochromatin is gene-poor, it is not devoid of genes. Models of heterochromatin structure must be able to accommodate the observation that the activity of these genes depends on the presence of normal heterochromatin structure; inactivation of HP1 leads to a loss of function of these genes. At the same time that we have noted specific biochemical features associated with heterochromatin formation, we have found that the same features can be found within euchromatic domains. For example, HP1 and H3-mK9 have been found not only in pericentric heterochromatin, but are also utilized in repressive regulation of some normal eukaryotic genes. Thus, one definition for *heterochromatic genes* may be those that are dependent on HP1 for optimal expression, whereas *euchromatic genes* might be defined as those exhibiting a loss of expression on association with HP1. As more genes are discovered that map to heterochromatic domains, it will be of interest to see if this pattern holds for other biochemical marks as well.

A critical question now under intense study is that of targeting heterochromatin formation: how is the pattern of differential chromatin packaging established? Recent data indicate that small interfering RNAs may play a role here, in addition to the regulation achieved by the RNA interference system by targeting transcription products for degradation (posttranscriptional silencing). A similar small RNA fraction could interact either with DNA in heterochromatin, for example, repeated sequences or transposable elements, or with proteins enriched in heterochromatin. Some chromodomain-containing proteins, notably MOF, can interact with RNA. Most compelling, mutations in several known genes participating in the formation of such small RNAs affect heterochromatin

silencing and centromeric function in the yeast *S. pombe*. One prerequisite for the formation of such small RNAs is the formation of long double stranded RNA, for example by bidirectional transcription. Interestingly, many transposable elements (commonly overrepresented in heterochromatin domains) are capable of bidirectional transcription. Thus heterochromatin formation may have derived from the need to silence invading transposons and retroviruses, to be adapted later in evolution to help create structures such as the centromere, and to help regulate gene expression throughout the genome. Experiments during the next several years should clarify many of the issues raised above.

Keywords

HAART
Highly Active Antiretroviral Therapy – an aggressive anti-HIV treatment usually including a combination of three or more drugs that are targeted at different steps in the HIV life cycle.

Multidrug-resistant HIV Strain
A strain of HIV resistance to at least two or more different classes of drugs.

Allosteric Binding Site
A site or a cavity on an enzyme other than its substrate binding site or active site.

Peptidomimetic
A small chemical compound that is designed to mimic a peptide in order to be recognized by an enzyme as its natural substrate.

Nucleoside
Nucleoside is an organic molecule consisting of a heterocyclic base (a purine or a pyrimidine) and a pentose sugar.

Nucleotide
A nucleotide is an organic molecule consisting of a heterocyclic base (a purine or a pyrimidine), a pentose sugar, and a phosphate group.

Transition State
An activated state of a molecule that has partly undergone a chemical reaction. Enzymes are thought to bind and stabilize the transition state, thus lowering the energy of activation needed to drive the reaction to completion.

Lipodystrophy
A disorder of adipose (fatty) tissue characterized by a selective loss of body fat. Patients with lipodystrophy have a tendency to develop insulin resistance, diabetes, a high triglyceride level (hypertriglyceridemia), and fatty liver.

Cytochrome P-450
A superfamily of hundreds of closely related heme proteins found throughout the phylogenetic spectrum, from animals, plants, fungi, to bacteria. In animals, these P-450 enzymes serve two major functions: (1) biosynthesis of steroids, fatty acids, and bile acids and (2) metabolism of endogenous and a wide variety of exogenous substrates, such as toxins and drugs (biotransformation).

Although significant progress has been made in the treatment of HIV infection, we are still far from wining the battle. The combination of highly active antiretroviral therapy (HAART) in compliant patients comes close to stopping virus evolution; however, eradication of the infection has not been achieved because of the persistence of latent HIV-1 in resting memory CD4 + T cells. Moreover, several factors including the emergence of multidrug-resistant HIV strains, drug toxicity, the patient's ability to adhere to the prescribed therapy, and expensive medication have necessitated a reason to develop novel drugs and novel approaches to combat HIV infection.

Currently, the HAART regimen consists of nucleoside and nonnucleoside reverse transcriptase (RT) combined with protease (PR) inhibitors. This article summarizes all currently approved drugs for HIV-1 infection as well as drugs that have made significant progress in clinical trials but have not yet been approved. Where appropriate, their mechanism of action, mechanism of resistance, and toxicity are discussed

1 Reverse Transcriptase Inhibitors

HIV-1 RT is a heterodimeric enzyme of 1000 amino acid residues. RT (reverse transcriptase) has been an attractive and highly explored drug target for AIDS chemotherapy. Of the 19 currently available FDA approved drugs, 11 are targeted at RT. This enzyme plays a vital role in the HIV replication cycle by catalyzing the conversion of viral RNA into a double-stranded, complementary DNA through at least three different enzymatic reactions. In the first step, RT catalyzes the conversion of the single-stranded viral RNA to a double strand of RNA:DNA hybrid using its RNA-dependent DNA polymerase activity. In the second step, RT generates a single-stranded DNA chain complementary to the viral RNA by the hydrolysis of a previously formed strand of RNA:DNA hybrid through its RNase H activity. Finally, using its DNA-dependent DNA polymerase activity, RT generates a second DNA chain to complete the formation of a double-stranded viral DNA. RT inhibitors prevent the formation of double-stranded viral DNA (proviral DNA) from the single-stranded viral RNA.

2 Nucleoside Reverse Transcriptase Inhibitors (NRTIs) and Nucleotide Reverse Transcriptase Inhibitors (NRTIs)

Both NRTIs (nucleoside reverse transcriptase inhibitors) and NtRTIs (nucleotide reverse transcriptase inhibitors) inhibit the catalytic activity of RT by directly interacting with the deoxynucleoside triphosphate (dNTP) substrate binding site of the RT after metabolic conversion to their corresponding 5′-phosphate derivatives (for NRTIs) and diphosphate derivatives (for NtRTIs). NRTIs and NtRTIs are not antiviral as such. They must be phosphorylated by host cellular kinases to form the 5′-triphosphates and are referred to as *prodrugs*. Currently, 7 NRTIs and an NtRTI (Tenofovir) are in clinical use (Figs. 1 and 2). The clinically used NRTIs include zidovudine, stavudine, zalcitabine,

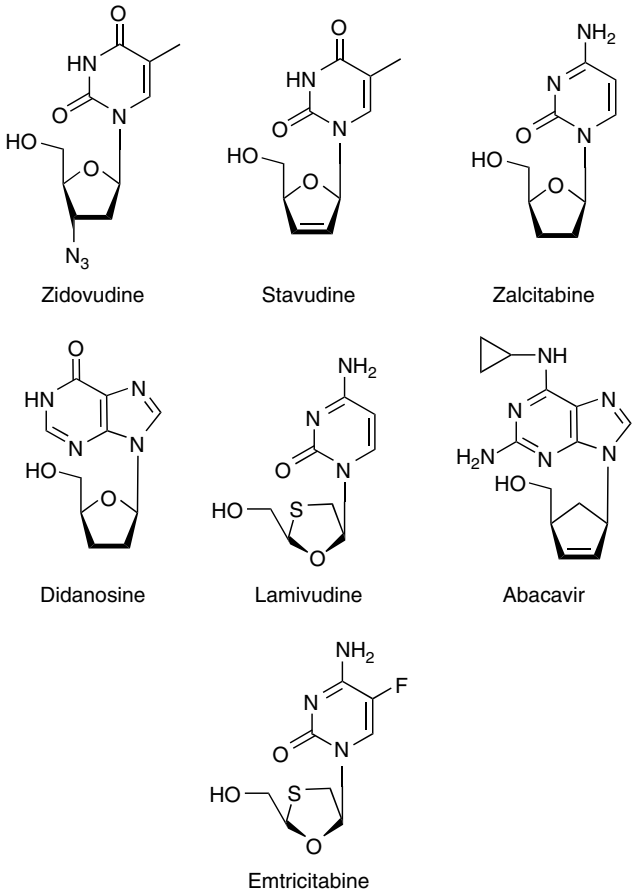

Fig. 1 Structures of FDA approved NRTIs.

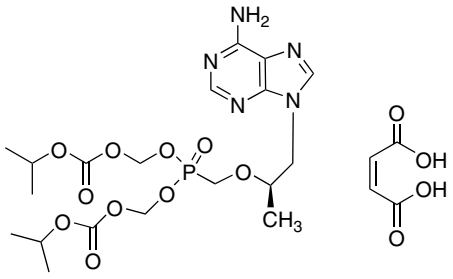

Fig. 2 Structure of Tenofovir disoproxil fumarate.

didanosine, lamivudine, abacavir, and emtricitabine (Table 1). Owing to considerable differences in their structures, NRTIs and the NtRTI utilize different enzymes for intracellular conversion to their active drug forms, and subsequently follow different metabolic pathways to be excreted. For example, thymidine analog, zidovudine (AZT) is converted to its 5′-monophosphate (AZTMP) form by

Tab. 1 Clinically used NRTIs, NtRTIs, and NNRTIs.

Zidovudine (AZT), Retrovir®	GlaxoSmithKline	DNA chain termination	HIV-1 and HIV-2
Didanosine (ddI), Videx®	Bristol Myers-Squibb	DNA chain termination	HIV-1 and HIV-2
Zalcitabine (ddC), Hivid®	Hoffmann-La Roche	DNA chain termination	HIV-1 and HIV-2
Stavudine (d4T), Zerit®	Bristol Myers-Squibb	DNA chain termination	HIV-1 and HIV-2
Lamivudine (3TC), Zeffix®	GlaxoSmithKline	DNA chain termination	HIV-1 and HIV-2, HBV
Abacavir (ABC), Ziagen®	GlaxoSmithKline	DNA chain termination	HIV-1 and HIV-2
Emitricitabine (FTC), Emtriva®	Gilead Sciences	DNA chain termination	HIV and HBV
Tenofovir disoproxil fumarate (bis(POC)PMPA), Viread®	Gilead Sciences	DNA chain termination	HIV-1 and HIV-2, various other retroviruses and HBV
Nevirapine, Viramune®	Boehringer Ingelheim	Binding to an "allosteric" pocket, nonsubstrate binding site of HIV-1 RT	HIV-1
Delavirdine, Rescriptor®	Pfizer	Binding to an "allosteric" pocket, nonsubstrate binding site of HIV-1 RT	HIV-1
Efavirenz, Sustiva®, Stocrin®	Bristol Myers-Squibb	Binding to an "allosteric" pocket, nonsubstrate binding site of HIV-1 RT	HIV-1

thymidine kinase. The phosphorylation of AZTMP to AZTDP is catalyzed by cellular thymidylate (dTMP) kinase. Finally, AZTDP is converted to AZTTP by cellular nucleoside 5′-diphosphate (NDP) kinase.

In general, clinically used RT inhibitors are analogs of natural nucleotides (dNTPs) substrates. After metabolic conversion to their corresponding phosphate forms, NRTIs, and NtRTIs compete with natural dNTP substrates for incorporation into the growing DNA chain. As a result of the incorporation into the growing DNA chain by RT, the growth of the DNA chain is terminated. This is due to the lack of a 3′-hydroxyl group on the sugar moiety of NRTIs and NtRTI. The drugs act as DNA chain terminators and inhibit the catalytic activity of RT. All NRTIs and the NtRTI are believed to proceed with a similar mechanism to inhibit RT, and thereby suppress the replication of HIV.

A major clinical problem with the current NRTIs and NtRTI is the emergence of resistant viral strains. The imposed drug pressure and the inherent lack of a proofreading mechanism by RT are the driving forces for emergence of drug-resistant HIV strains. The resultant RT mutations are specific to each NRTI and therefore show decreased sensitivity to the corresponding NRTI. The RT mutations that cause resistance are diverse. Therefore, an RT mutant resistant to a particular NRTI can be inhibited by another NRTI. This condition is strategically exploited by designing combination regimens to effectively bring down viral loads in patients with resistant HIV viral strains. However, cross-resistant RT mutants have also been isolated for a number of NRTIs and NtRTI combinations. The emergence of drug-resistant HIV RT strains is attributed to two different kinds of mechanisms of drug resistance. Specific mutations in the RT substrate binding site can selectively prevent incorporation of the NRTI into the growing DNA chain, while the enzyme still retains the ability to incorporate the natural dNTP substrates. HIV RT achieves this discriminative ability through specific mutations in the substrate binding site that cause steric hindrance to the NRTI, and therefore selectively interfere with its incorporation. The M184V and M184I mutation of RT both confer high-level clinical resistance to lamivudine, and represent a classical example of RT mutation (Table 2). The second known mechanism of drug resistance is the excision of NRTI from the growing DNA chain. The drug resistant RT efficiently incorporates the NRTI into the DNA chain, which temporarily blocks DNA growth. However, the NRTI is subsequently removed (excised) from the blocked DNA chain allowing elongation to proceed. The best-known example of this kind of resistance is the excision of AZTMP, which causes AZT resistance.

A common problem with NRTIs and NtRTI-based treatment is long-term drug related toxicity. Long-term toxicities associated with these drugs are mostly related to the intracellular phosphorylation of the drugs. The treatment with NRTIs and NtRTI is associated with a range of toxicities thought to result from the inhibition of mitochondrial polymerase-γ, leading to impaired synthesis of the mitochondrial enzymes that generate ATP through oxidative phosphorylation (Table 2). All the NRTIs are associated with hyperlactatemia and lactic acidosis. Patients taking stavudine and didanosine seem to be at greater risk than patients taking other NRTIs. The NRTIs and NtRTI mitochondrial toxicity is organ and drug specific, possibly as a result of variability in intracellular drug penetration and the metabolism to the triphosphate form.

Tab. 2 Major drug resistant mutations, toxic side effects, and drug interactions of clinically used NRTIs and NtRTI.

Name	*Mutations associated with resistance*	*Toxic side effects*	*Drug interactions*
Zidovudine	M41L, E44D, D67N, K70R, V118I, L210W, T215Y/F, K219Q/E	Anemia, granulocytopenia, myopathy, hepatic transaminase elevations, headaches, fatigue, nausea	Should not be combined with Stavudine (Zerit®)
Didanosine	K65R, L74V	Peripheral neuropathy, pancreatitis, lactic acidosis, diarrhea, headaches, vomiting, rash, headaches, high blood pressure	Should not be combined with Zalcitabine (Hivid®), Stavudine (Zerit®)
Zalcitabine	K65R, T69D, L74V, M184V	Peripheral neuropathy, pancreatitis, rash, chest pain, fever, nausea, changes in liver function, and mouth sores, headaches, high blood pressure	Should not be combined with Stavudine (Zerit®), Lamivudine (Zeffix®), Didanosine (Videx®)
Stavudine	M41L, E44D, K65R, D67N, K70R, V118I, L210W, T215Y/F, K219Q/E	Lipodystrophy, peripheral neuropathy, lactic acidosis, diarrhea, fever, fatigue, headaches, high blood pressure	Should not be combined with Zidovudine (Retrovir®), Zalcitabine (Hivid®), Didanosine (Videx®)
Lamivudine	E44D, K65R,V118I, M184V/I	Nausea, diarrhea, abdominal pain, headaches, fatigue, neutropenia, nausea, vomiting, sleeping disorders	Should not be combined with Zalcitabine (Hivid®),
Abacavir	K65R, L74V, Y115F, M184V	Hypersensitivity, gastrointestinal disturbance, rash, fever, fatigue, headache, nausea, and vomiting	
Emitricitabine	K65R, M184V/I	Lactic acidosis, fatty liver, skin color changes (rarely), headache, diarrhea, nausea, rash	Should not be combined with Lamivudine (Zeffix®),
Tenofovir disoproxil	K65R	Increased levels of creatine and transaminases, reduced bone-mineral density, nausea, vomiting, and loss of appetite, headaches, high blood pressure	Should not be combined with Lamivudine (Zeffix®), Didanosine (Videx®), Abacavir (Ziagen®)

3
Nonnucleoside Reverse Transcriptase Inhibitors (NNRTIs)

The NNRTIs (nonnucleoside reverse transcriptase inhibitors) prevent HIV replication by binding to a pocket (nonsubstrate or allosteric binding site) that is located in close proximity to the natural dNTP substrate binding site of RT. They do not compete with the natural dNTP substrates for the binding site. The binding of NNRTIs to this pocket induces significant distortion in the substrate binding site of RT. This in turn decreases the catalytic activity of the enzyme. NNRTIs slow down the polymerase activity of RT, and thereby suppress the HIV replication by binding to a nonsubstrate binding pocket on RT. Hence, NNRTIs do not act as DNA chain terminators, and they do not need to be incorporated into the growing DNA chain to inhibit the catalytic activity of RT.

The three NNRTIs approved by the FDA for clinical use are nevirapine, delavirdine, and efavirenz (Fig. 3). Despite their structural diversity, all the NNRTIs show high specificity for HIV-1 RT, over that of HIV-2 RT and other DNA polymerases. The NNRTIs are very different from NRTIs and NtRTIs in many aspects; as (1) they do not bind to the substrate binding site, (2) they do not need to be converted to an active form, (3) they are very selective to HIV-1 RT, and (4) they are less toxic *in vivo*. The critical problem with NNRTIs is the rapid onset of viral resistance when administered alone because of the high mutation rate of RT. Mutations specifically occur at amino acid residues surrounding the NNRTI binding pocket. The most common amino acid mutations that confer resistance to NNRTIs are those that directly interfere with RT drug binding (Fig. 4). For this reason, NNRTIs are clinically used only in combination with other drugs, most often with NRTIs or NtRTIs.

Nevirapine and efavirenz are metabolized by the liver cytochrome P450 family of enzymes. Delavirdine happens to be an inhibitor of the cytochrome P450. Nevirapine and efavirenz are broken down by the liver and can subsequently interact with other drugs metabolized by the liver. The

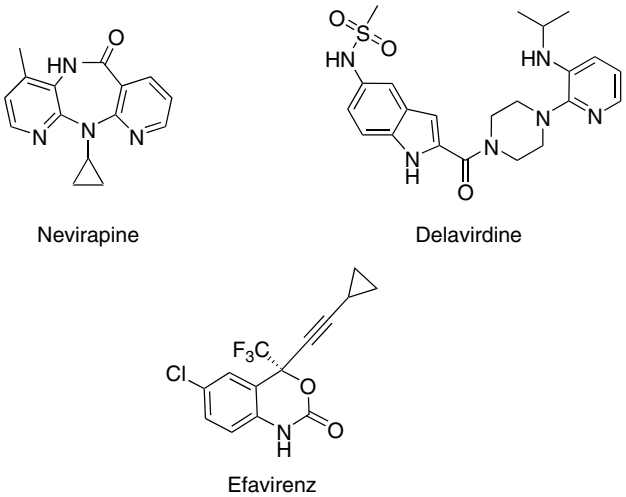

Fig. 3 Structures of FDA approved NNRTIs.

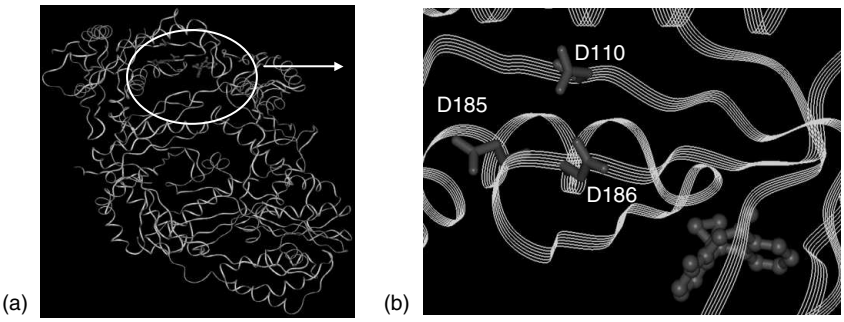

Fig. 4 The crystal structure of HIV-1 RT complexed with nevirapine (PDB1S1X). Nevirapine is a nonnucleoside inhibitor and binds to an allosteric (nonsubstrate) binding pocket. The ribbon model shows RT enzyme (a) while three aspartate residues at polymerase active site of RT and the adjacent nevirapine binding pocket are enlarged. (b) Catalytically important three aspartate residues (D110, D185, and D186) are represented as stick models. The ball and stick model represents the binding mode of nevirapine.

Tab. 3 Observed drug resistant mutations and side effects of NNRTIs.

NNRTIs	*Mutations associated with resistance*	*Toxic side effects*
Nevirapine	L100I, K103N, V106A/M, V108I, Y181C/I, Y188C/L/H, G190A	Skin rash, Stevens-Johnson syndrome (rare), diarrhea, fever, depression, headache
Delavirdine	K103N, V106M, Y181C, Y188L, P236L	Maculopapular rash, Stevens-Johnson syndrome (rare), headache, gastrointestinal disorders
Efavirenz	L100I, K103N, V106M, V108I, Y181C/I, Y188L, G190S/A, P225H	Central nervous system stimulation, dizziness

serious side effects caused by the clinical use of these drugs are liver damage and other closely related problems. Other common side effects associated with NNRTI treatment are maculopapular rash, hepatic transaminase elevations, and central nervous system complaints such as dizziness (Table 3).

4 Protease Inhibitors

HIV-1 PR is an aspartic protease with two catalytically essential aspartic acid residues in its active site (from each monomer). The catalytically active PR (protease) exists as a homodimer. The two identical subunits of 99 amino acid residues (monomer) are noncovalently associated in a twofold C_2 symmetric fashion (Fig. 5). PR proteolytically cleaves the polyproteins that are encoded by the HIV *gag* and *pol* genes in the final stage of the viral life cycle. Inactivation of PR by either mutational or chemical inhibition leads to the production of immature, noninfectious viral particles. Therefore, the function of PR is essential for proper virion assembly and maturation.

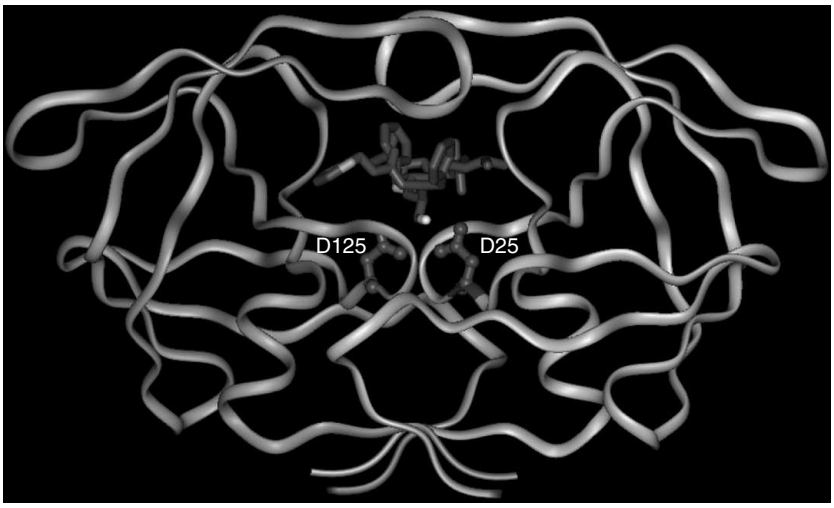

Fig. 5 Crystal structure of HIV-1 protease (PR) complexed with ritonavir (PDB1HXW). The two monomers of the PR are represented as ribbon models (yellow and magenta). The two catalytic aspartate residues (D25 and D125) are rendered as ball and stick models while the ritonavir is represented by a stick model. The hydroxyl group of the ritonavir occupies the space between two aspartate residues. (See color plate p. xxvi).

PR inhibitors (PIs) prevent HIV replication by competitively binding to and inhibiting the proteolytic activity of PR.

The seven peptidomimetic PIs approved by the FDA for clinical use are saquinavir, ritonovir, indinavir, nelfinavir, amprenavir, lopinavir, and atazanavir (Fig. 6). The rationale behind the development of the PIs came from the architecture of the PR active site and the tetrahedral transition state of the bound substrate. Despite their structural diversity, all the clinically used PIs possess a pseudosymmetric diaminoalcohol core unit (Fig. 6). All PIs currently used in therapy contain a hydroxyl group that is correctly positioned between the two catalytic aspartate residues in order to both donate and accept a hydrogen bond (Table 4). This closely resembles the tetrahedral transition state of substrate cleavage (Fig. 5). All PIs are reversible inhibitors that compete with natural substrate. They have a higher binding affinity to PR than peptide substrates because PR binds to the transition state to a greater degree than the substrate itself.

Although PIs belong to a potent class of antiviral drugs, their clinical effectiveness has been hampered by the emergence of drug resistant and cross-resistant PR mutants. Specific mutations at PR active site that affect PI binding are responsible for the emergence of drug-resistant HIV strains. Continued replication under the pressure of PI, and the high transcriptional error rate by HIV RT are attributed to the emergence of drug-resistant HIV mutants (Table 5).

The primary hepatic enzymes responsible for the metabolism of all the clinically used protease inhibitors are the cytochrome P450 isoenzymes such as CYP 3A4, CYP2C9, CYP2D6. Some PIs are potent inhibitors or inducers of the cytochrome P450 isoenzymes. As a result, PIs affect the metabolic processes and

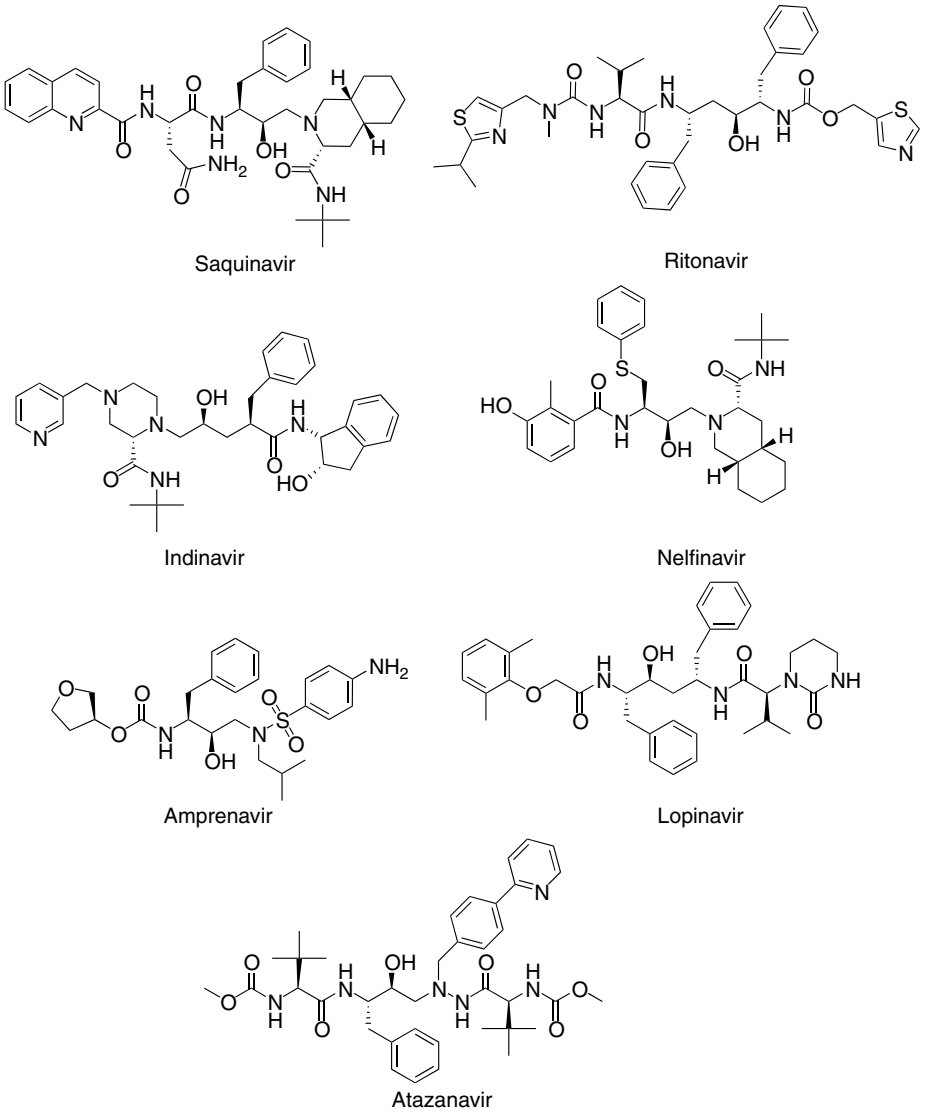

Fig. 6 Structures of FDA approved PIs.

blood levels of other drugs that are also metabolized by the cytochrome P450 isoenzymes. Consequently, the metabolism and blood level of PIs are also affected by drugs that inhibit the cytochrome P450 isoenzymes. For example, ritonovir, a potent inhibitor of the cytochrome P450 3A4, slows down the body's processing of lopinavir, and boosts blood levels of lopinavir. This coformulation of lopinavir and ritonavir, known as *Kaletra*, was approved by the FDA and is highly effective in bringing down the viral loads in HIV-1 infected patients. This ritonovir boosted-PI is

a powerful anti-HIV drug and is currently favored as a first-line therapy. The serious side effects that are associated with clinical use of PIs are liver toxicity, lipodystrophy, hyperglycemia, hyperlipidemia, and sexual dysfunction (Table 5). The other common side effects caused by PIs are nausea, diarrhea, upset stomach, and heartburn. Lipodystrophy is fat redistribution with accumulation of neck and abdominal fat that is usually associated with loss of facial, buttocks, and extremity fat. The probable reason for this condition is suppression of breakdown of the nuclear sterol regulatory element binding proteins (nSERBP) by PIs. Suppression of the breakdown of nSERBP results in increased fatty acid and cholesterol biosynthesis in liver, which leads to lipodystrophy and insulin resistance in adipose tissue.

5 Integrase Inhibitors

HIV-1 integrase (IN) catalyzes two crucial steps required for the integration of viral DNA into the host chromosome. In the first step, while in the cytoplasm of an infected cell, IN selectively cleaves two nucleotides (GT) from the 3′ terminal end of the viral cDNA, in a reaction known as 3′-*processing*. Immediately after translocation to the nucleus as a component of the preintegration complex, IN randomly inserts the viral cDNA into the host genome. This reaction is referred to as *strand transfer or integration*. Hence, the interactions of IN with viral cDNA are sequence specific, but that with the host DNA are sequence independent. Consequently, their respective binding sites are expected to be geometrically and spatially different within the catalytic site of IN.

Currently, there are no FDA approved drugs targeting IN on the market. IN is an important and attractive antiretroviral drug target because there are no cellular homologs to IN, and the reactions catalyzed by IN are unique. A major concern with AIDS treatment is the emergence of drug-resistant viral strains, and the highly active antiretroviral therapy fails to eradicate the virus in HIV-infected patients. Therefore, addition of novel drugs, targeting alternative steps in the viral replication processes such as integration, to existing multidrug regimens would improve the outcome of treatment. Previously, several structurally diverse compounds were reported as IN inhibitors. Among all reported IN inhibitors, the β-diketoacid class of compounds has proved to be of most promise. Two of them, S-1360 and L-870, 810 have entered into clinical studies (Fig. 7). These compounds are believed to inhibit IN by interacting

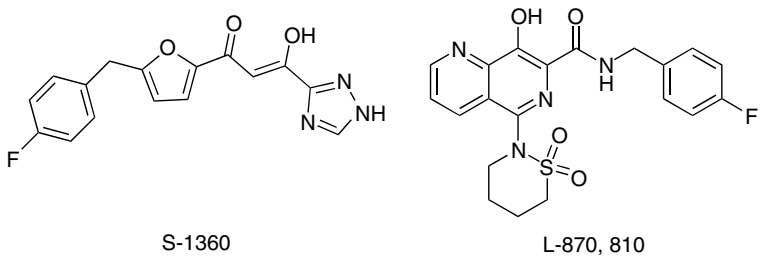

Fig. 7 Structures of integrase inhibitors.

Tab. 6 HIV-1 integrase inhibitors in clinical trials.

Name	*Pharmaceutical company*	*Mechanism of action*	*Resistant mutations*	*Status*
S-1360	Shionogi/GSK	Selective inhibition of strand transfer reaction of HIV-1 integrase	Q148K, I151L, N155S	Phase II
L-870, 810	Merck	Selective inhibition of strand transfer reaction of HIV-1 integrase	F121Y, T125K, V72I, V151I	Phase I

with the active site Mg^{2+} ion, and are selective inhibitors of the strand transfer reaction. These compounds showed antiviral activity against a variety of HIV strains expressing significant resistance to all of the currently available FDA approved drugs for HIV/AIDS, including NRTIs, NNRTIs, and PIs. After passing preliminary safety assessment studies, S-1360 and L-870, 810 compounds entered into clinical trials (Table 6).

6
HIV Entry Inhibitors

The process of HIV-1 entry into cells is conveniently divided into three main stages. First is the attachment of the virus to the host cell surface, mediated by the interaction of the viral envelope glycoprotein gp120 with the host T-lymphocyte cell surface protein CD4. This is an obligatory step for efficient infection of cells by HIV-1. Second is the interaction of the virus with chemokine coreceptors mediated by exposed domains of gp120. This is the result of induced conformational changes in gp120 upon its initial interactions with the CD4 receptor. Third, is the fusion of the virus and host cell membranes mediated by gp41. The above-mentioned steps are complex molecular events, and have been considered for the design of HIV-1 entry inhibitors (Table 7).

6.1
Inhibitors of GP120-CD4 Interactions

The HIV envelope glycoprotein gp120 interaction with the host cell surface CD4 protein, the principal receptor for HIV, is an indispensable step for HIV entry into cells. The CD4 protein belongs to the superfamily of immunoglobulin (Ig) like proteins, and is expressed primarily on T lymphocytes and macrophages. Binding of CD4 to gp120 is mediated by the interaction of N-terminal domain of CD4 with a cavity in gp120, located at the junction of both the inner and outer domains as well as bridging sheet of gp120 (Fig. 8). Detailed understanding of this docking process was elucidated through the recently solved crystal structure of a molecular complex consisting of an HIV-1 gp120 core, a two-domain fragment of CD4 and the Fab fragment of 17b, a neutralizing monoclonal antibody (Fig. 8). Currently, there are no FDA approved drugs targeting the gp120-CD4 interaction available for clinical use. However, two drugs, FP-21399 and BMS-488043, designed to interfere with gp120-CD4 interaction, have recently entered into clinical studies. An attachment

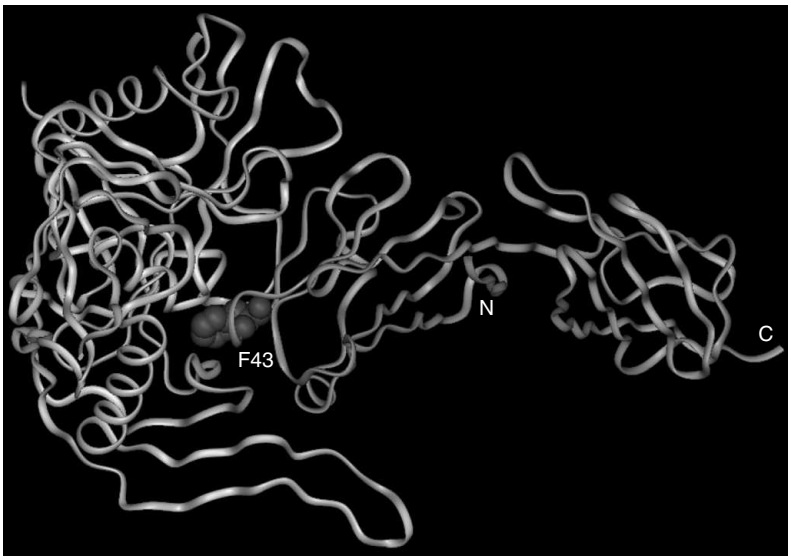

Fig. 8 The ribbon diagram of crystal structure shows binding of gp120 (magenta) to CD4 receptor (yellow). The F43 (shown as CPK model) of CD4 protrudes into a hydrophobic cavity on gp120. In this orientation, the CD4 binding cavity on gp120 is clearly visible. (See color plate p. xxvi).

inhibitor, PRO-542, a recombinant tetravalent CD4-IgG2 fusion protein, is currently under Phase II clinical trials. Another recently reported small-molecule attachment inhibitor BMS-378806, also targets viral entry by inhibiting the docking of the gp120 to the CD4 receptor through a specific and competitive mechanism. In fact, BMS-378806 binds to gp120 at or near the CD4 binding pocket. TNX-355, a monoclonal anti-CD4 antibody is also currently in Phase II clinical trials. This monoclonal antibody inhibits HIV replication by blocking the interaction between gp120 and CD4.

6.2 Chemokine Receptor Antagonists

Apart from the CD4 receptor, HIV needs a coreceptor for entry into host cells. The chemokine receptors CXCR4 and CCR5 have been identified as the principal coreceptors for HIV-1. The CCR5 receptor was found to mediate HIV-1 entry into macrophages and primary T cells (M or R5 tropic), whereas CXCR4 was shown to allow HIV-1 entry into primary T cells and T cell lines (T or X4 tropic). Both CCR5 and CXCR4 are members of the superfamily of guanine-nucleotide-binding protein-coupled receptors (GPCR). The importance of CCR5 for HIV-1 transmission and pathogenesis was established by reports demonstrating that individuals homozygous for a defective CCR5 allele are highly resistant to HIV-1 infection, whereas heterozygotes progress slower toward AIDS, probably due to a reduced surface expression of CCR5. However, targeting these cellular receptors for antiviral therapy has potential for serious side effects due to perturbations in the natural function of these receptors. Interestingly, knockout of the CCR5 gene in mice does not induce significant pathology. On the other hand, the deletion of CXCR4 in mice resulted in an embryonic lethal phenotype, suggesting that CXCR4 function is essential in mammals. Currently, there are no FDA approved drugs targeting either the CCR5 or the CXCR4 binding to gp120. The CCR5 antagonists under clinical studies are TAK-220, SCH-D, UK-427857, and GW873140 (AK-602 or ONO-4128). The small-molecule CXCR4 antagonists currently in clinical trials are KRH-1636, AMD3100, and AMD070. AMD3100, a bistetraazamacrocycle, is a potent inhibitor of HIV entry that specifically inhibits infection of X4 HIV-1 and HIV-2 strains but not R5 HIV-1 isolates. This molecule is a highly specific CXCR4 antagonist, and is currently in Phase II clinical trials. It is yet unclear whether AMD3100 competes directly for the gp120-binding site on CXCR4, or whether the compound prevents gp120 binding by inducing conformational changes in CXCR4 through an allosteric mechanism.

6.3 Viral Fusion Inhibitors

The binding of gp120 to CD4 and coreceptors triggers conformational changes in gp41, another HIV envelope glycoprotein, which leads to fusion of viral and host cell membrane. The exact mechanism of the conformational changes in gp41 that drive membrane fusion is not clearly understood. The most widely accepted model proposes that upon CD4 and coreceptor engagement, gp41 forms a prehairpin intermediate, in which the fusion peptide is inserted into the cellular membrane. This transient structure can be targeted by peptide inhibitors to disrupt the fusion process. Drugs targeting structural intermediates required for fusion can efficiently

block viral infection. Enfuvirtide (T-20) is a peptide based HIV-1 fusion inhibitor approved by the FDA for the treatment of HIV infection in treatment-experienced patients. Enfuvirtide, a synthetic peptide of 36 amino acids, binds to the HIV gp41 and blocks the fusion of viral and cellular membranes. Enfuvirtide competitively binds to the first heptad repeat (HR1) region of gp41, preventing the formation of a six-helix bundle, which is critical for membrane fusion to occur. Enfuvirtide exhibited synergistic activity when combined with individual antiretroviral agents, including zidovudine, lamivudine, nelfinavir, and indinavir. The most frequent adverse effects associated with the use of enfuvirtide are reactions at the injection site. Mutations in the HR1 region of gp41 envelope gene that are associated with resistance to Enfuvirtide include G36D/S, I37V, V38A/M, Q39R, N42T, and N43D. An enfuvirtide related peptide, T-1249, also binds to the N-terminal heptad repeat region (N-HR) of gp41 and blocks HIV-1 replication. T-1249 is currently in Phase I/II clinical studies.

7 Other Potential Drug Targets

7.1 HIV-1 Nucleocapsid Protein as a Drug Target

HIV-1 nucleocapsid (HIV-1 NC) protein is a small, highly basic protein with two conserved zinc (Zn^{2+}) finger domains. HIV-1 NC is generated during protease processing of the *gag* polyprotein that occurs during retrovirus maturation. HIV-1 NC is essential for the viral life cycle. This is due to its role in recognizing viral RNA from cellular RNA for dimerization and packaging, promoting binding of the essential t-RNA primer to the primer site, stimulating reverse transcription, and protecting viral RNA from nucleases. Mutations in HIV-1 NC are not tolerated, and a strong relationship has been established between the three-dimensional organization of NC and its biological functions. Mutations in the zinc finger domains of NC lead to a complete loss of infectivity. Hence, HIV-1 NC is a potential antiretroviral-drug target. Compounds that interfere with Zn^{2+} binding (destabilization of Zn^{2+} tetrahedral geometry), or eject the Zn^{2+} ion from the zinc finger domains of HIV-1 NC cause the denaturation of protein. This is lethal for the virus, and leads to formation of noninfective virions. Over the years several compounds have been reported that selectively interact with viral zinc finger proteins, but none of them have successfully reached advanced clinical studies.

7.2 Targeting HIV-1 Proteins Vif, Tat, and Rev

HIV accessory and regulatory proteins such as Vif, Tat, and Rev share a common function as adapter molecules to recruit cellular factors for various steps in the viral replication cycle. It is known that Vif-defective viruses are capable of entering target cells but encounter an early block in virus replication before integration of the viral DNA into the host genome. Currently, none of the inhibitors of Vif, Tat, and Rev have advanced to clinical trials.

Keywords

Homeobox
A conserved sequence of about 180 nucleotides that is found in many developmental control genes.

Homeodomain
The protein domain encoded by the homeobox. It is a DNA-binding domain.

Homeotic Gene
Mutations in a homeotic gene cause transformations – homeotic transformations – of groups of cells or body segments. For example, the cells of a segment are transformed into cell types of a different body segment. A large number of homeotic genes are homeobox genes, but not all. And not all homeobox genes are homeotic genes.

HOX Cluster
A gene cluster in animals made up of Antennapedia-type homeobox genes (Hox genes). The genes in this cluster function primarily in the pattern formation along the anterior–posterior body axis.

Hox Genes
The homeobox genes that reside in the Hox cluster(s). This designation should be reserved for use in vertebrates.

POU Genes
A special well-known class of homeobox genes that encode two domains, a POU-specific domain and a POU homeodomain. The POU-specific domain binds DNA also.

TALE Homeobox Genes
A special subgroup of homeobox genes, whose homeodomain is normally 63 amino acids long, rather than the standard 60, because of three extra amino acids between helix 1 and helix 2. Highly conserved from plants to animals.

Homeodomain proteins are DNA-binding proteins that play major roles in many developmental processes of animals as well as fungi and plants. The homeodomain is a protein domain of about 60 amino acids that binds DNA. Proteins containing a homeodomain can regulate the expression of other genes in development and differentiation. Hundreds of homeobox genes have been identified, and they can be grouped into many different classes. Often, other conserved protein domains are found linked to a homeodomain. Several particular types of homeobox genes lie next to each other on the chromosome in clusters. The best-known cluster, the HOX cluster, is found in all bilateral animals. Vertebrates contain four HOX clusters that have arisen through duplication in early vertebrate evolution; its genes are called *Hox* genes. Lower chordates, insects, and nematodes have only one HOX cluster. Of particular interest is that many of the HOX cluster genes function in the process of pattern formation along the anterior–posterior body axis. However, a lot of homeobox genes are not found in clusters and do not function in pattern formation, but play roles in the determination of cell fates and cell differentiation. Homeobox genes thus perform key roles for all aspects of the development of an organism.

1 What is a Homeodomain?

1.1 Introduction

Since their discovery in 1983, homeobox genes, and the homeodomain proteins they encode, have turned out to play important roles in the developmental processes of all multicellular organisms. While certainly not the only developmental control genes, they have been shown to play crucial roles from the earliest steps in embryogenesis – such as setting up an anterior–posterior gradient in the egg of the fruit fly *Drosophila melanogaster* – to the very latest steps in cell differentiation – such as the differentiation of neurons in the nematode *Caenorhabditis elegans*. They are found in plants, fungi, and all animal phyla. Since their original discovery, hundreds of homeobox genes have been described, and this article, which is based on previous compilations, attempts to give an overview of these genes.

1.2 The Homeodomain Sequence

The homeobox was originally described as a conserved DNA motif of about 180 bp. The protein domain encoded by the homeobox, the homeodomain, is, accordingly, about 60 amino acids long. The first genes found to encode homeodomain proteins were the *Drosophila* developmental control

genes, in particular, homeotic genes, from which the name "homeo" box was derived. However, many homeobox genes are not homeotic genes; the homeobox is a sequence motif, while "homeotic" is a functional description for genes that cause homeotic transformations when mutated. Further, not all homeotic genes are homeobox genes.

As more and more homeobox-containing genes were isolated, it became clear that the homeodomains of closely related genes had sequence similarity that extended upstream and/or downstream of the standard core of 60 amino acids. In contrast, when highly divergent homeodomain sequences are compared, the sequence similarity does not extend over the full 60 residues. Figure 1(a) shows a consensus sequence that is based on a compilation of 346 homeodomain sequences. The numbering scheme beneath this consensus is in accordance with that used in the publications that describe the homeodomain structure.

An analysis of the frequency of each amino acid at each position of the homeodomain indicates that certain positions are significantly more conserved than others. A summary of these conserved amino acids is given in Fig. 1(b). Under each consensus (i.e. most common) amino acid, other amino acids that occur at that position are listed in decreasing order of frequency. Amino acids found in fewer than five sequences have been omitted. The gray background bars highlight those residues in each position, which can be found in at least 85% or more of the homeodomain sequences. For example, at position 47, the two hydrophobic residues isoleucine (I) and valine (V) are found in 333 of the 346 sequences (96%), while a threonine (T) is found in only 9 sequences (2.6%). In addition, two sequences have an asparagine (N) residue and two have a histidine (H) and are thus not even shown in Fig. 1(b). In such a way, one can identify positions where amino acids with particular properties, such as hydrophobic residues (e.g. position 47), are highly conserved.

The conserved positions in Fig. 1(b) have been arbitrarily divided into three groups, depending on how many different amino acids occur at a particular position in this compilation. There are seven very highly conserved positions (¤). However, only two positions are almost totally invariant, the tryptophan (W) residue at position 48 and the asparagine (N) residue at position 51. Occasionally, the tryptophan (W) can be substituted by a phenylalanine (F) residue. Three other positions predominantly contain one amino acid but occasionally permit substitutions: position 16, normally a leucine (L), can accommodate a methionine(M) or other hydrophobic residues; positions 20 and 49, normally phenylalanine (F) residues, can be substituted by tyrosine (Y) or other hydrophobic residues. Position 53 is almost invariably an arginine (R), though lysine (K) is possible. Position 57 accommodates either an arginine (R) or a lysine (K) residue, although other residues are possible.

A second group of highly conserved positions (▼) has fewer than six different amino acids at a particular position. Six such positions are found: 5, 26, 40, 45, 47, and 57. Thirteen positions fall into the third group of moderately conserved positions (∗), which can have up to nine different amino acids at a particular position. However, those positions of the homeodomain that are not especially marked by any of the three previous symbols are not completely devoid of information. Often, while many different amino acids can occur at a particular

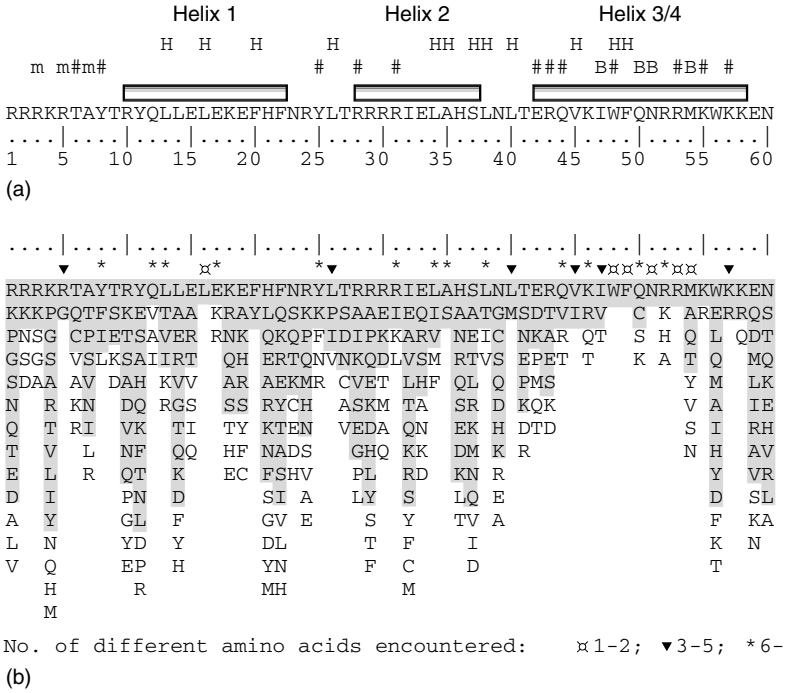

Fig. 1 (a) A homeodomain consensus sequence (presented in single-letter code, as are all subsequent sequence figures) that is based on 346 homeodomain sequences. The standard numbering scheme is shown beneath the consensus. The three α-helices (a composite derived from the structures of the Antp, en, and MATα2 homeodomains) are shown schematically as cylinders above the consensus. Special symbols mark amino acids positions that play a role for intramolecular or protein–DNA contacts of the homeodomain; they are shown above the consensus and have the following meanings: amino acids designated ''H'' contribute to the hydrophobic core that is responsible for the tertiary structure of the homeodomain; residues designated ''B'' contact bases in the major groove and are responsible for sequence-specific DNA contacts; residues designated ''m'' make contacts in the minor groove; the pound sign (#) indicates residues that contact the sugar-phosphate backbone of the DNA. (b) Amino acids encountered at a given position in the homeodomain (based on 346 sequences). For each position, the amino acid most frequently encountered is listed at the top, while other amino acids are listed beneath in decreasing order of their frequency of occurrence. Residues in the shaded group are found in at least 85% of the 346 homeodomain sequences. Amino acids occurring fewer than five times are not shown. The symbols on top indicate highly conserved positions: ¤, most highly conserved positions, with only one or two different amino acids found at that position; ▼, highly conserved position, with three to five different amino acids at that position; *, conserved positions, with six to nine different residues at that position. *Note*: the 346 selected sequences for this compilation are biased toward animal, in particular, Antp-like homeodomain sequences.

position, some amino acids appear to be excluded. For example, at position 1, no tyrosine (Y) or tryptophan (W) has been found in the 346 sequences examined.

These 60 positions, especially the more conserved ones, define the typical homeodomain. Residues in the DNA-binding region of helix 3 (see Sect. 1.2) are especially conserved and constitute a ''trademark'' for the homeodomain. The sequence compilation shown here is mainly composed of animal homeodomains, with a bias toward Antennapedia-like sequences. Nevertheless, even plant homeodomain sequences show a similar pattern of conserved residues, although amino acid frequencies at particular positions may vary from the one presented here.

1.3 Structure of the Homeodomain

The underlying reason for the conservation of particular amino acids is the structure of the homeodomain. Several structures have been determined using either NMR or X-ray analysis, for example, fly Antennapedia (Antp), fushi tarazu (ftz), engrailed (en), or mammalian PBX1, Oct1, HNF1α, or yeast MATα2. The core of the homeodomain consists essentially of three α-helices. The NMR studies of the Antp homeodomain identified a kink in the third helix, at position 52/53, such that this helix is considered to consist of two separate helices, helix 3 and helix 4. The three α-helices are represented as shaded cylinders above the consensus sequence in Fig. 1(a).

The various symbols (H, B, #, m) above the helices in Fig. 1(a) give a schematic summary of various contacts made by the amino acids of the homeodomain, as deduced from structural and genetic data. Not every homeodomain makes every interaction shown; in particular, DNA contacts can be slightly different in different homeodomains. The three helices are held together by a hydrophobic core. The residues marked by ''H'' take part in the formation of this hydrophobic core. Helix 2 and helix 3 are connected by a tight turn called a *helix-turn-helix motif* that is also found in prokaryotic gene regulatory proteins. Helix 1 is connected to helix 2 by a loop, which contains three extra amino acids in TALE (three amino acid loop extension) homeodomains (see below). Helix 1 lies approximately parallel to helix 2, and also crosses over helix 3. At the crossover area, the highly conserved residues in helix 1 interact with the highly conserved residues tryptophan and phenylalanine of helix 3. Figure 2 is a schematic representation of how the three helices pack against one another and how they lie with respect to the DNA.

1.4 DNA-binding Properties

NMR and X-ray analysis of DNA–protein complexes for several homeodomain proteins have allowed the identification of the residues critical for sequence-specific contacts and contacts to the DNA backbone. These studies have been complemented by *in vivo* and *in vitro* studies on the DNA-binding properties of homeodomains and confirm the importance of some of the DNA–amino acid contacts that have been deduced by the structural studies.

Helix 3, also termed the *recognition helix*, lies in the major groove of the DNA and plays the most important role in making sequence-specific contacts (Fig. 2). Those residues that make sequence-specific contacts are indicated with a ''B'' in Fig. 1(a) above the consensus. Many other residues make nonsequence-specific contacts to the

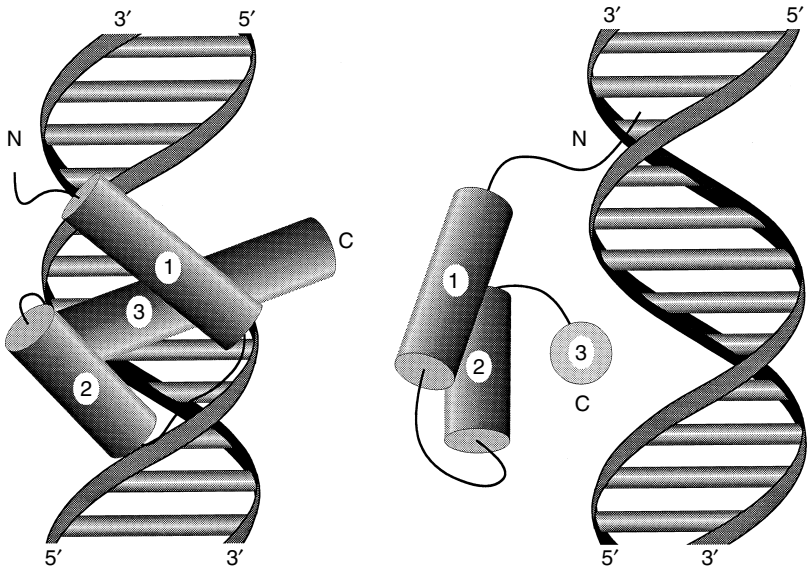

Fig. 2 Two views of a simplified schematic representation of the three-dimensional structure of the homeodomain and how it binds to DNA. The three numbered cylinders show helices 1, 2, and 3; N marks the amino terminus of the homeodomain and C the carboxyl terminus. The double helix represents the DNA. The left panel is rotated by about 90° with respect to the right panel.

DNA backbone (indicated by ''#''). As can be seen, these residues are not only found in helix 3 but also in helix 2 and at the amino terminus of the homeodomain. The amino terminus reaches into the minor groove of the DNA, where the residues marked ''m'' can contact the DNA in the minor groove. A very critical residue that determines sequence specificity is found at position 9 of helix 3 (i.e. position 50). Exchanging this amino acid can cause drastic changes in the type of DNA sequence that is recognized by a particular homeodomain. Several sequences that are bound by homeodomains have been identified. A binding site for Antp is AGCCATTAGA, with the core being ATTA (TAAT on the other strand). This core-binding site is too small for providing sufficient specificity to activate only the intended target genes. Different types of homeodomain proteins employ different strategies to solve this problem. Some combine several DNA-binding domains in a single protein, some form homodimers, and many form heteromeric complexes with homeodomain or other types of transcription factors.

1.5 Classification of Homeodomains

The purpose of comparing and classifying the sequences of homeobox-containing genes is to determine evolutionary relationships between the different genes to find out which genes are orthologous between different species and which ones merely belong to the same group or class. With the advent of many completed genomes, this is now a much easier task. The resulting classification allows one to

examine how structural conservation in evolution correlates with functional conservation. In order to arrange the homeodomain sequences into logical groups, the terms *superclass*, *class*, and *family* are used here. Their use reflects the hierarchy of relationships such that a superclass encompasses several classes and a class can be further subdivided into families.

Figure 3 shows a comparative tree that has been derived from a much larger tree; this tree presents selected genes of different classes and families. Such a tree provides an easy means of grouping homeodomain sequences for classification. All superclasses and classes as well as most families presented here are well conserved in evolution, and members can be found in deuterostomes as well as protostomes. In fact, a very useful criterion for the identification of families is that they should be conserved over a long time period. The ideal definition for a family would be that its members were derived from a single gene in the ancestor of protostomes and deuterostomes; classes would comprise several families with common features. If a homeobox gene, whose homeodomain sequence is very divergent from others, is only found within related species of a particular phylum, it indicates that it is probably derived from another homeobox gene, for example, by duplication, and has undergone rapid evolutionary changes. Generally, classes of homeobox genes have less than 50 to 55% sequence identity within their homeodomains when compared to other classes. Within a particular family, the homeodomain can be 80 to 90% identical from flies to vertebrates. The genes within the Antp superclass, particularly those of the HOX cluster, are somewhat of an exception since they tend to be highly conserved, especially those in the center of the cluster.

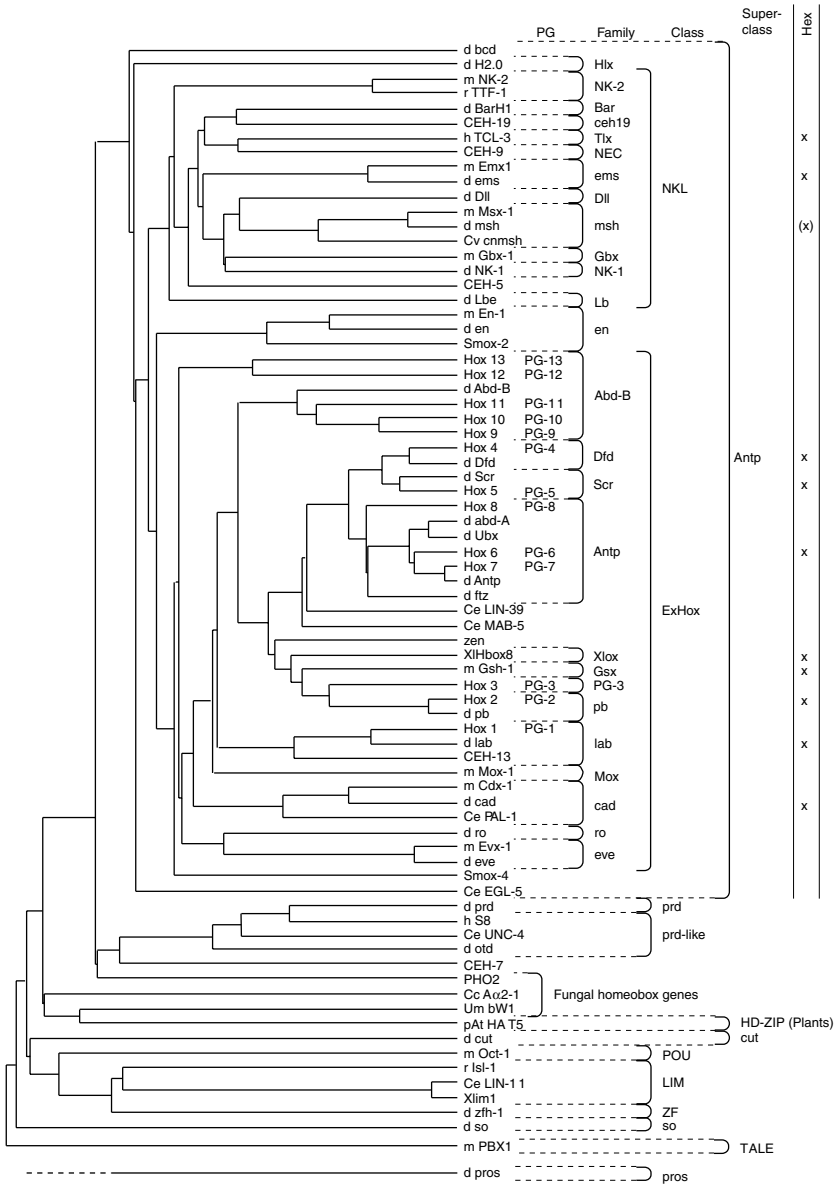
Many of the homeodomain classes have additional conserved protein domains or motifs outside of the homeodomain. Such sequence motifs, which sometimes can be even more conserved than the homeodomain itself, provide extra criteria to differentiate the various classes of homeobox genes. Figure 4 shows a schematic diagram of homeobox gene families and classes that encode special conserved sequence motifs outside of the homeodomain. Homeodomain proteins of several families of the Antp superclass contain a short ''Hexapeptide'' motif upstream of the homeodomain. Conserved domains found in other classes can be 100 amino acids or longer, and for many, the structure has been determined either by X-ray crystallography or NMR analysis. Some of these domains can even be repeated within the same homeodomain protein, and some homeodomain proteins have several homeodomains.

The sections that follow introduce the various classes of homeobox genes. Figures 5 and 6 present an overview of homeodomain sequences of selected genes from the various classes and families. Detailed descriptions of expression patterns and gene functions are beyond the scope of this article, and the reader is referred to the literature and PubMed (http://www.ncbi.nlm.nih.gov/).

1.6 Atypical Homeodomains

Quite a number of homeobox genes have now been found whose homeodomain is different in length from the typical 60 amino acids. In order to get optimal alignments for these homeodomains, extra amino acids have to be looped out in various places. This was first noticed in yeast MATα2, where a better alignment

of the helix 1 region to the consensus could be achieved by looping out three extra amino acids. As already pointed out, X-ray crystallography of the MATα2 homeodomain revealed that its structure is indeed very similar to en and Antp, and that three amino acids are in fact looped out between helix 1 and helix 2. Many genes have now been isolated that have three extra amino acids between helix 1 and helix 2 from a variety of organisms (Fig. 6, TALE superclass, see below).



Extra amino acids have also been found in several genes between helix 2 and helix 3, for example, in the liver transcription factor LFB1(HNF1α), in the prospero protein, in fly defective proventriculus (dve), or in plant HD-ZIP III proteins (see 4.2, 5.4, 10.2). The homeodomains of the fungal proteins bE and AαZ have additional amino acids both between helix 1 and helix 2 and between helix 2 and helix 3. Homeodomain sequences that require such insertions and/or deletions are referred to as *atypical homeodomains* to contrast them from the typical homeodomain with 60 amino acids. However, ''atypical'' by itself is not a useful descriptor for the classification of homeobox genes. In fact, insertions and deletions in the homeodomain have occurred many times independently in evolution. Even within typical classes or families, such divergence is possible. For example, unlike other sine oculis (so) class homeobox genes, the *C. elegans* so class protein CEH-35 has one extra residue between helix 1 and helix 2.

2
The Antennapedia Superclass

This is a large group of genes that are related to one of the first homeobox genes discovered, Antennapedia. A number of these genes are organized into gene clusters, that is, the HOX cluster, the ParaHox cluster, which is a ''sister'' of the HOX cluster, and the NK cluster. However, many homeobox families within the Antp superclasses do not reside in a cluster and are referred to as *dispersed*. Common features of the Antp superclass genes are that they do not encode large conserved domains outside of the homeodomain but only small motifs. The Hexapeptide motif is found in genes of the HOX, ParaHox, and NK cluster, as well as in dispersed genes, such as the ems family (Fig. 4). The Hexapeptide is usually separated by an intron from the homeodomain. Other small motifs are found in NK-2 homeodomain proteins or in en homeodomain proteins (Fig. 4). Within the Antp superclass, two major groups can be distinguished, the Extended Hox (ExHox) class of genes with the Hox, Mox, Evx, and ParaHox genes and the NKL class of genes with the NK cluster genes and gene families such as NK-2, Dll, ems, NEC, Bar, Xnot, Gtx, Gbx, and Mnx (Fig. 3).

2.1
The HOX Cluster

The first, and also best-known, homeobox genes are the homeotic selector genes of *D. melanogaster* that are organized into

Fig. 3 Comparative tree showing different families and classes of homeobox genes. The tree is based on the aligned homeodomain sequences. The more similar the two homeodomain sequences are to each other, the shorter the horizontal distance is from the branch point to the endpoint, which represents the homeodomain of a particular gene. Conversely, the longer a branch of the tree is, the less related that branch is to other homeodomains. At the endpoints of individual branches, examples of particular homeobox genes for selected families and classes are given. The paralogue groups of the vertebrate HOX clusters are indicated by PG, and parentheses mark the families, classes, and superclasses, which are indicated on the right. Those genes that are not assigned to classes are either divergent members of existing classes (e.g. LIN-39, MAB-5, zen) or are orphans for which the origin has not been determined (e.g. CEH-7, CEH-5). The column at the right indicates families having a Hexapeptide upstream of the homeodomain.

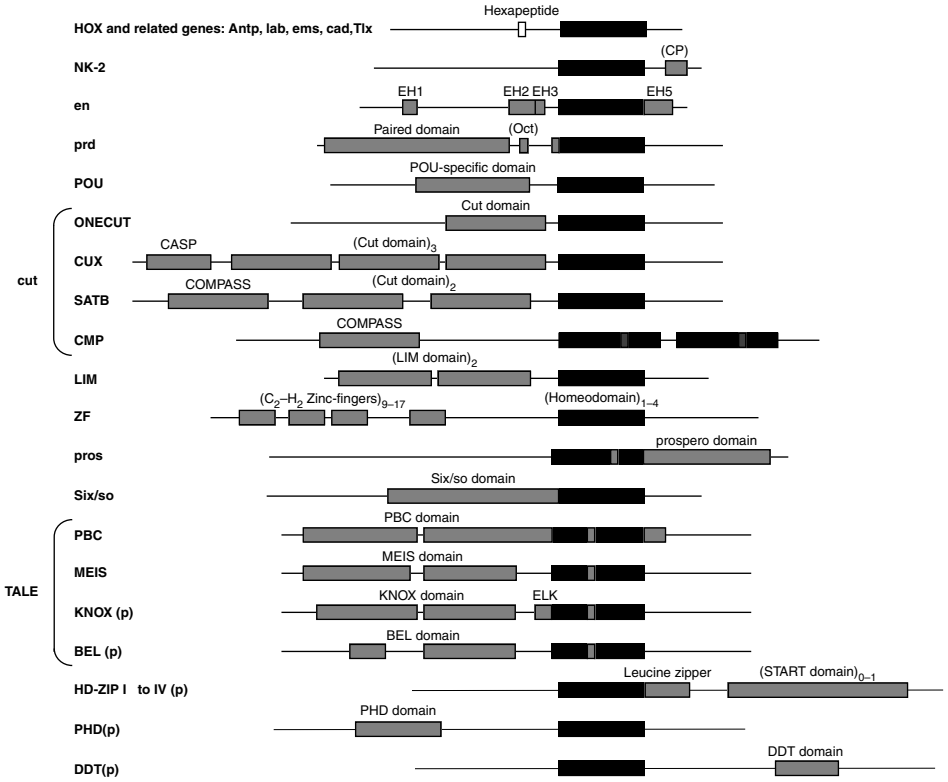


Fig. 4 Schematic representation of families and classes of homeobox genes encoding conserved motifs outside of the homeodomain. On the left are the names of the different selected families and classes. The black box represents the homeodomain, and insertions within the homeodomain, either between helix 1 and 2 or helix 2 and 3, are indicated by differently patterned boxes. The other boxes with different patterns represent conserved sequence motifs specific to individual classes or superclasses. The length of the boxes is approximately proportional to the size of the domains. The connecting linker regions (black lines) can be substantially different between genes and do not reflect true length. The Hexapeptide is found in several different families within the Antp superclass, mainly in *Hox* genes. In several instances, the number of domains can vary. The CP motif in the NK-2 family and the Oct motif in the paired class do not occur in all members of the class/family. In the ZF class, the number of zinc fingers as well as the number of homeodomains (one to four) can vary substantially, and the zinc fingers can be interspersed with the homeodomains. The lower part of the panel shows plant homeodomain classes (p). The plant HD-ZIP III and IV classes have a START domain, HD-ZIP I and II do not.

two complexes, the Antennapedia complex (ANT-C) and the Bithorax complex (BX-C), summarily referred to as the *homeotic gene complex* (HOM-C). In *Drosophila*, only one such cluster is found, while higher vertebrates have four homologous clusters, each on a different chromosome (Fig. 7). These clusters have been termed *HOX clusters* in vertebrates, and the usage of naming these clusters ''HOX clusters'' has now been expanded to include other animal phyla, including *Drosophila*. The

four vertebrate HOX clusters originally arose through duplications of a single cluster at some point in early vertebrate evolution. Indeed, in the cephalochordate amphioxus (lancelet), only a single cluster has been found. On the other hand, one has to note that in teleost fish, extra HOX clusters (as well as extra homeobox genes and extra copies of many other genes) are found since it is thought that the ancestor of this group of fish underwent an extra genome duplication event. HOM-C related clusters of homeobox genes are now commonly referred to as *HOX cluster* in all species where they are found. However, the use of the word Hox to name individual genes in the HOX cluster should be restricted to vertebrates.

Figure 7 shows the *C. elegans, Drosophila,* and vertebrate HOX clusters. The genes in the four vertebrate clusters (termed *HOXA, HOXB, HOXC, HOXD*) can be aligned such that 13 groups are formed that are highly related based on their sequence. These groups are referred to as *paralogue groups 1 to 13* (PG-1 to PG-13), and individual genes in mice are named *HoxA-1, HoxA-2,* and so on. Each cluster has missing genes for some of the paralogue groups. This suggests that the vertebrate cluster duplication took place after all 13 groups had formed and that during or after the duplication events, some genes were lost. Overall, there are 39 Hox genes in mouse and human. In vertebrates, but not in flies, the Evx genes are closely linked to the HOX cluster, indicating that these genes are part of the ancestral HOX cluster, although this gene family has a separate name. Likewise, the Mox genes are also associated with the HOX cluster, albeit at the opposite end (not shown). Both Evx and Mox genes are referred to as *extended HOX cluster genes.*

The lines and brackets in Fig. 7 between the fly and vertebrate clusters indicate how the Hox genes are related to the fly genes. For example, the *Drosophila* gene *labial* is the orthologue of the PG-1 genes *HoxA-1, HoxB-1,* and *HoxD-1* in mice. Some genes have no direct one-to-one correspondence. For example, the fly gene *Abd-B* is homologous to PG-9 through PG-13, probably due to a separate expansion of the Abd-B family genes in the deuterostome lineage. Further, the central genes in the cluster (PG-6 to PG-8, and ftz to abd-A) may have arisen independently by gene duplication within each phyla. A degenerate HOX cluster containing seven homeobox genes has been found in the nematode *C. elegans*. Two Abd-B family genes have split from the cluster, while the remaining five homeobox genes have also been separated into two subgroups by a series of other genes (Fig. 7). Recently, it has become apparent that an ancestor of *C. elegans* seems to have lost several homeobox genes since in several other nematode species, additional homeobox genes are present in the HOX cluster.

The genes of the HOX cluster have received particular attention not only because they are clustered on the chromosome but also because the way they are physically clustered correlates with the way they are expressed along the anterior–posterior body axis (Fig. 8). Thus, genes at one end of the cluster are expressed and function in the anterior body region, while, as one progresses along the chromosome, the genes are expressed and function further and further toward the posterior of the animal. This colinearity of genes and expression pattern is even more striking when one considers that the Hox genes are all transcribed in the same direction. Thus, the genes of PG-13 are usually referred to as the genes of the 5′ end of

the cluster and are expressed posteriorly, while those of PG-1 are at the 3′ end of the cluster and are expressed anteriorly.

The Hexapeptide, also known as *Pentapeptide*, was first described in HOX cluster genes. All genes in the HOX cluster, apart from the Abd-B family of genes encode this short conserved peptide motif upstream of the homeodomain. The Hexapeptide has a conserved core sequence of six amino acids (Fig. 9). Apart from the Hexapeptide, HOX cluster gene families often possess additional sequence conservation outside of the homeodomain. In particular, short stretches of the amino-terminal region of several families are conserved; in some cases, the similarity exists even between different families.

2.1.1 **Labial (lab) Family**

The labial family of genes is located at the 3′ end of the cluster. The *Drosophila* lab homeodomain is 80 to 85% identical to the PG-1 group genes, and the homeodomains of the lab family are 55 to 67% identical to other HOX cluster genes. The lab family genes encode distinct Hexapeptide sequences upstream of the homeodomain (Fig. 9).

2.1.2 **Proboscipedia (pb) Family**

The vertebrate paralogue group PG-2 is closely related to the *Drosophila* gene *pb*. Members of this family seem to be lacking in *C. elegans*, suggesting that homeobox genes can be lost in evolution.

2.1.3 **PG-3 Family**
